Aims and scope

Physica B (Condensed Matter) contains papers and review articles in the realm of physics of condensed matter. Both experimental and theoretical contributions are invited, although theoretical papers should preferably be related to experimental results.

Abstracted/indexed in:

Current Contents: Physical, Chemical and Earth Sciences; *Aluminium Industry Abstracts*, *EI Compendex Plus*, *Engineered Materials Abstracts*, *Engineering Index*, *INSPEC*, *Metals Abstracts*, *Physics Briefs*.

Subscription information

Physica B (ISSN 0921-4526) is published monthly. For 2001, volumes 291–306 are scheduled for publication. Subscription prices are available upon request from the Publisher. A combined subscription with *Physica A*, *Physica C*, *Physica D* and *Physica E* is available at a reduced rate. Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by surface mail except to the following countries where air delivery via SAL is ensured: Argentina, Australia, Brazil, Canada, China, Hong Kong, India, Israel, Japan, Malaysia, Mexico, New Zealand, Pakistan, Singapore, South Africa, South Korea, Taiwan, Thailand, USA. For all other countries air mail rates

are available upon request. Please address all enquiries regarding orders and subscriptions to:

Elsevier Science B.V.
Customer Support Department
P.O. Box 211, 1000 AE Amsterdam
The Netherlands
Telephone: +31-20-485 3757; Telefax: +31-20-485 3432

Claims for issues not received should be made within six months of our publication (mailing) date.

Author enquiries

For enquiries relating to the submission of articles (including electronic submission), the status of the accepted articles through our Online Article Status Information System (OASIS), author Frequently Asked Questions and any other enquiries relating to Elsevier Science, please consult <http://www.elsevier.com/locate/authors/>

For specific enquiries on the preparation of electronic artwork, consult <http://www.elsevier.com/locate/authorartwork/>

Contact details for questions arising after acceptance of an article, especially those relating to proofs, are provided when an article is accepted for publication.

US Mailing Notice

Physica B (ISSN 0921-4526) is published monthly by Elsevier Science, Molenwerf 1, P.O. Box 211, 1000 AE Amsterdam, The Netherlands. The annual subscription price in the USA is US\$ 4961 (valid in North, Central and South America only), including air speed delivery. Periodicals postage paid at Jamaica, NY 11431.

USA postmasters: Send address changes to *Physica B*, Publications Expediting Inc., 200 Meacham Avenue, Elmont, NY 11003.

Airfreight and mailing in the USA by Publications Expediting Inc., 200 Meacham Avenue, Elmont, NY 11003.

Preface and Acknowledgements

These are the proceedings of the 21st International Conference on Defects in Semiconductors, ICDS-21, which was held at the Justus-Liebig University of Giessen, Germany, between July 16–20, 2001. The ICDS had not been held in Germany since 1974, when it took place in Freiburg under the chairmanship of Prof. A. Seeger (ICDS-8). Since then the ICDS has been held every two years in the USA, Japan or Europe. Compared to the two preceding conferences in Aveiro, Portugal (1997) and in Berkeley, USA (1999), the conference in Giessen expanded considerably as to the number of participants as well as contributions, demonstrating that the field is timely, active and striving.

In Giessen there were 350 registered participants from 40 countries with strong representations from Germany (88), Japan (51), USA (36), Russia (27), Great Britain (20), Ukraine (17) and Poland (11). The rather large number of participants from Eastern European countries was made possible by special support given to the ICDS by the Deutsche Forschungsgemeinschaft, the University of Paderborn, the University Society of Giessen, the USA (Air Force, Navy) and many other institutions and industrial firms. Without that support, which is gratefully acknowledged, the participation of so many Eastern Europeans and also of many young scientists would not have been possible.

At the conference four plenary talks were delivered on the first day, followed by 86 oral contributions in two parallel sessions and 272 posters in two poster sessions as well as 8 “late news” posters, bringing the total number of accepted contributions to 384.

The poster sessions were held after the oral afternoon session later in the afternoon and into the evening with plenty of space also for small discussion groups at tables in the large hall between the lecture theatres. There was ample food and drink available during the poster sessions so that most delegates stayed much longer than the official time, having and enjoying intense and lively discussions.

The scientific scope was wider than before in that, apart from more traditional silicon problems and a strong representation of group III-nitrides, ZnO appeared as a new focus and the silicon carbide community concerned with defects found its way to the ICDS for the first time in larger numbers. Two of the plenary talks were on theory of defects reflecting the trend that theory has made much progress during the last years to provide almost an “instrumental” arm to defect studies. The other two were on applications of the knowledge on impurity diffusion in SiGe to produce world-record-fast devices and on a historical view into ZnO, which all of a sudden is experiencing an enormous revival.

The proceedings will again be published in an archival journal, *Physica B*, following the preceding ICDS. All papers were refereed during the conference, an enormous task, for which the organizers would like to thank the many referees, but also the vast majority of delegates who delivered their papers at the beginning of the conference. Special thanks to Dr. D. Hofmann who took care of the Proceedings.

It gives us great pleasure to thank the members of the International Advisory and Programme committees for their active advice and input into the programme. We thank in particular those members of the Programme Committee (Profs. Emtsev, Jantsch, Nielsen and Stutzmann) who came to Giessen for two days to help to shape the final programme. We also thank the session chairs for their help to keep the sessions on time and to ensure good discussions.

We owe the smooth running and the harmonious atmosphere at the conference to the many members of the Giessen physics department who worked with so much enthusiasm in the local conference team under

the guidance of the conference secretary, Dr. A. Hofstätter, and the supervision of the treasurer, Dr. E. Pitt. A big thankyou to all of you.

Last but not least we would like to thank all the attendees for making this another exciting conference and for conveying us the optimistic feeling that the next conference in this series will be as lively and interesting as this one was.

Bruno K. Meyer, *Chair*
Johann-Martin Spaeth, *Chair*

Supporters of ICDS-21	x
1. Plenary papers	
The fascinating dynamics of defects in silicon S.K. Estreicher, P.A. Fedders and P. Ordejón	1
Thermal double donors in Si and Ge R. Jones, J. Coutinho, S. Öberg and P.R. Briddon	8
Misfortune, challenge, and success: defects in processed semiconductor devices H. Cerva, M. Engelhardt, M. Hierlemann, M. Pölzl and T. Thenkl	13
2. Gallium nitride	
<i>2.1. Doping</i>	
Optical study of GaN:Mn co-doped with Mg grown by metal organic vapor phase epitaxy R.Y. Korotkov, J.M. Gregie, B. Han and B.W. Wessels	18
Photoluminescence and lattice location of Eu and Pr implanted GaN samples T. Monteiro, C. Boemare, M.J. Soares, R.A. Sá Ferreira, L.D. Carlos, K. Lorenz, R. Vianden and E. Alves	22
Investigation of the defect structure of GaN heavily doped with oxygen R.Y. Korotkov, F. Niu, J.M. Gregie and B.W. Wessels	26
Mn-related absorption and PL bands in GaN grown by metal organic vapor phase epitaxy R.Y. Korotkov, J.M. Gregie and B.W. Wessels	30
Photoluminescence properties of Er doped GaN H. Przybylińska, A. Kozanecki, V. Glukhanyuk, W. Jantsch, D.J. As and K. Lischka	34
Compensation mechanism in MOCVD and MBE grown GaN:Mg H. Alves, M. Böhm, A. Hofstaetter, H. Amano, S. Einfeldt, D. Hommel, D.M. Hofmann and B.K. Meyer	38
Green and red emission in Ca implanted GaN samples T. Monteiro, C. Boemare, M.J. Soares, E. Alves and C. Liu	42
Study of dopant activation in bulk GaN:Mg R. Piotrkowski, E. Litwin-Staszewska, T. Suski and I. Grzegory	47

2.2. Point and extended defects

Magnetic resonance studies of defects in GaN with reduced dislocation densities E.R. Glaser, J.A. Freitas Jr., G.C. Braga, W.E. Carlos, M.E. Twigg, A.E. Wickenden, D.D. Koleske, R.L. Henry, M. Leszczynski, I. Grzegory, T. Suski, S. Porowski, S.S. Park, K.Y. Lee and R.J. Molnar	51
Radiation-induced defects in n-type GaN and InN V.V. Emtsev, V.Yu. Davydov, E.E. Haller, A.A. Klochikhin, V.V. Kozlovskii, G.A. Oganessian, D.S. Poloskin, N.M. Schmidt, V.A. Vekshin and A.S. Usikov	58
A radiation-produced defect in GaN displaying hyperfine structure with three Ga atoms G.D. Watkins, L.S. Vlasenko and C. Bozdog	62
Electron paramagnetic resonance of GaN detected by recombination afterglow U. Rogulis, S. Schweizer and J.-M. Spaeth	66
Defect-related noise in AlN and AlGaIn alloys S.T.B. Goennenwein, R. Zeisel, S. Baldovino, O. Ambacher, M.S. Brandt and M. Stutzmann	69
Positively charged muonium centers in aluminum and gallium nitrides R.L. Lichti, S.F.J. Cox, E.A. Davis, B. Hitti and S.K.L. Sjøe	73
Ga vacancies in electron irradiated GaN: introduction, stability and temperature dependence of positron trapping K. Saarinen, T. Suski, I. Grzegory and D.C. Look	77
Influence of defects in low-energy nitrogen ion beam assisted gallium nitride thin film deposition J.W. Gerlach, S. Sienz, W. Attenberger and B. Rauschenbach	81
ODEPR and yellow luminescence intensity in GaN under high pressure K. Michael, U. Rogulis, F.K. Koschnick, Th. Tröster, J.-M. Spaeth, B. Beaumont and P. Gibart	85
Investigation of structural defects of thick GaN grown by flow-modulated hydride vapor-phase epitaxy W. Zhang, H.R. Alves, T. Riemann, M. Heuken, P. Veit, D. Meister, W. Kriegseis, D.M. Hofmann, J. Christen and B.K. Meyer	89
Characterization of Al _x Ga _{1-x} N layers grown by molecular beam epitaxy H. Kim and T.G. Andersson	93
AFM study of lattice matched and strained InGaAsN layers on GaAs Y. Park, M.J. Cich, R. Zhao, P. Specht, H. Feick and E.R. Weber	98
In-plane and in-depth nonuniformities in defect distribution in GaN and InGaIn epilayers M. Godlewski, E.M. Goldys, G. Pozina, B. Monemar, K. Pakula, J.M. Baranowski, P. Prystawko and M. Leszczynski	102
Strain relaxation in GaN _x P _{1-x} alloy: effect on optical properties I.A. Buyanova, W.M. Chen, E.M. Goldys, M.R. Phillips, H.P. Xin and C.W. Tu	106
Positron annihilation in AlN and GaN N.Yu. Arutyunov, V.V. Emtsev, A.V. Mikhailin and V.Yu. Davidov	110
Distribution of the lateral correlation length in GaN epitaxial layers J. Kozłowski, R. Paszkiewicz, R. Korbutowicz and M. Tlaczala	114

2.3. Impurities

The role of oxygen and hydrogen in GaN B. Clerjaud, D. Côte, C. Naud, R. Bouanani-Rahbi, D. Wasik, K. Pakula, J.M. Baranowski, T. Suski, E. Litwin-Staszewska, M. Bockowski and I. Grzegory	117
Hydrogen vibrational lines in HVPE GaN M.G. Weinstein, F. Jiang, M. Stavola, B.B. Nielsen, A. Usui and M. Mizuta	122
Properties of carbon as an acceptor in cubic GaN U. Köhler, M. Lübbbers, J. Mimkes and D.J. As	126
Electrically active defects in AlGaIn alloys grown by metalorganic chemical vapor deposition D. Seghier and H.P. Gislason	130

3. Silicon

3.1. Hydrogen

Electronic levels of isolated and oxygen-perturbed hydrogen in silicon and migration of hydrogen K.B. Nielsen, L. Dobaczewski, S. Søgård and B.B. Nielsen	134
Piezospectroscopic analysis of the hydrogen-carbon complexes in silicon O. Andersen, L. Dobaczewski, A.R. Peaker, K.B. Nielsen, B. Hourahine, R. Jones, P.R. Briddon and S. Öberg	139
Formation mechanism of hydrogen-induced (1 1 1) platelets in silicon Y.-S. Kim and K.J. Chang	143
Vibrational properties of H-related defects in silicon J.M. Pruneda, J. Junquera, J. Ferrer, P. Ordejón and S.K. Estreicher	147
Structural properties of hydrogen-induced platelets in silicon: a Raman scattering study E.V. Lavrov and J. Weber	151
Quadruplevoids in amorphous Si:H T. Krüger and A.F. Sax	155
New hydrogen-related radiation-induced deep-level center in boron-doped silicon N. Yarykin, O. Feklisova and J. Weber	159
Fermi-level dependence of formation of hydrogen molecules in crystalline silicon K. Ishioka, N. Umehara, T. Mori, K. Ohtsuka, M. Kitajima, K. Murakami and S. Hishita	163
Defects agglomeration in the vicinity of hydrogen-related vacancy-type complexes in proton-implanted silicon S.Zh. Tokmoldin and B.N. Mukashev	167
Multivacancies trapping hydrogen molecules T. Mori, K. Otsuka, N. Umehara, K. Ishioka, M. Kitajima, S. Hishita and K. Murakami	171
Defect-related photoinduced absorption in amorphous silicon E. Morgado	174
Hydrogen-induced formation of defects nanoclusters in crystalline silicon Kh.A. Abdullin, Yu.V. Gorelinskii and B.N. Mukashev	178

Low-temperature photoluminescence characterization of defects formation in hydrogen and helium implanted silicon at post-implantation annealing A.V. Mudryi, F.P. Korshunov, A.I. Patuk, I.A. Shakin, T.P. Larionova, A.G. Ulyashin, R. Job, W.R. Fahrner, V.V. Emtsev, V.Yu. Davydov and G. Oganessian	181
Hydrogen enhanced thermal donor formation in p-type Czochralski silicon: application to low temperature active defect-engineering A.G. Ulyashin, R. Job, I.A. Khorunzhii and W.R. Fahrner	185
On defects created in 45 keV H^+ -implanted n-type Cz Si: a fluence dependence and isochronal annealing study P.N.K. Deenapanray	190
DLTS study of defects in hydrogen plasma treated p-type silicon L. Wu and A.W.R. Leitch	193
Evidence for H_2^+ trapped by carbon impurities in silicon B. Hourahine, R. Jones, S. Öberg, P.R. Briddon, V.P. Markevich, R.C. Newman, J. Hermansson, M. Kleverman, J.L. Lindström, L.I. Murin, N. Fukata and M. Suezawa	197
The strange behavior of interstitial H_2 molecules Si and GaAs S.K. Estreicher, J.L. McAfee, P.A. Fedders, J.M. Pruneda and P. Ordejón	202
Raman scattering study of vacancy-hydrogen related defects in silicon E.V. Lavrov, J. Weber, L. Huang and B.B. Nielsen	206
On the nature of hydrogen-related centers in p-type irradiated silicon O. Feklisova, N. Yarykin, E.B. Yakimov and J. Weber	210
Simulation of hydrogen penetration in silicon under wet chemical etching O. Feklisova, S. Knack, E.B. Yakimov, N. Yarykin and J. Weber	213
Complexes of point defects and impurities in electron-irradiated CZ-Si doped with hydrogen A. Nakanishi, N. Fukata and M. Suezawa	216
Temperature dependences of line widths and peak positions of optical absorption peaks due to localized vibration of hydrogen Si M. Suezawa, N. Fukata, M. Saito and H. Yamada-Kaneta	220
Complexes of point defects and hydrogen generated by electron-irradiation of hydrogenated Si at low temperatures M. Suezawa, Y. Takada, T. Tamano, R. Taniguchi, F. Hori and R. Oshima	224
Observation of two coupled defect levels on the hydrogen-passivated Si (100) surface A.J. Reddy, J. Michel and L.C. Kimerling	228
<i>3.2. Doping and impurities</i>	
Terahertz emission from silicon doped by shallow impurities H.-W. Hübers, S.G. Pavlov, M.H. Rummeli, R.Kh. Zhukavin, E.E. Orlova, H. Riemann and V.N. Shastin	232
Mobility of interstitial B in Si analyzed by a stochastic reorientation model B. Ittermann, D. Peters, M. Füllgrabe, F. Kroll, H. Ackermann and H.-J. Stöckmann	236
Stress-induced splitting of the electronic level related to a platinum-hydrogen complex in silicon K. Fukuda, Y. Iwagami, Y. Kamiura, Y. Yamashita and T. Ishiyama	240

Valence force field analysis on nitrogen in silicon H. Harada, I. Ohkubo, T. Mikayama, Y. Yamanaka and N. Inoue	244
Spectroscopic characterization of implanted boron in microcrystalline silicon by β -NMR F. Mai, B. Ittermann, M. Füllgrabe, M. Heemeier, F. Kroll, K. Marbach, P. Meier, H. Mell, D. Peters, H. Thieß, H. Ackermann and H.-J. Stöckmann	248
Magnetic resonance and FTIR studies of shallow donor centers in hydrogenated Cz-silicon B. Langhanki, S. Greulich-Weber, J.-M. Spaeth, V.P. Markevich, B. Clerjaud and C. Naud	253
P-type doping of hydrogenated amorphous silicon films with boron by reactive radio-frequency co-sputtering Y. Ohmura, M. Takahashi, M. Suzuki, N. Sakamoto and T. Meguro	257
Dopant boron concentration dependence on electron irradiation enhanced defects in Czochralski silicon T. Tamano, F. Hori, R. Taniguchi, R. Oshima and K. Hoshikawa	261
Interstitial carbon reactions in n-Si induced by high-energy proton irradiation K. Kono, H. Amekura and N. Kishimoto	265
On the correlation character between the structure perfection and electroluminescent properties of terbium doped silicon monoxide films V.S. Khomchenko, L.I. Berejinskij and M.V. Sopinskyy	268
The control mechanism of the impurity agglomeration triggered by ion impacts S.T. Nakagawa	272
Optical absorption peaks observed in electron-irradiated n-type Si M. Suezawa, N. Fukata and A. Kasuya	276
Essential difference in concentration profile of Au in Si after annealing above or below 850°C M. Morooka	280
3.3. Oxygen	
Interaction between self-interstitials and the oxygen dimer in silicon J.L. Lindström, T. Hallberg, J. Hermansson, L.I. Murin, B.A. Komarov, V.P. Markevich, M. Kleverman and B.G. Svensson	284
Isotopic effects on vibrational modes of thermal double donors in Si and Ge L.I. Murin, J.L. Lindström, V.P. Markevich, T. Hallberg, V.V. Litvinov, J. Coutinho, R. Jones, P.R. Briddon and S. Öberg	290
Chemical and structural characterization of oxygen precipitates in silicon by infrared spectroscopy and TEM O. De Gryse, P. Clauws, O. Lebedev, J. Van Landuyt, J. Vanhellemont, C. Claeys and E. Simoen	294
Effect of oxygen on exciton transitions in silicon A.N. Safonov and G. Davies	298
Disturbance of oxygen by isovalent impurity atoms in silicon L.I. Khirunenko, V.A. Zasuha, Yu.V. Pomezov and M.G. Sosnin	301
Over-coordinated oxygen in the interstitial carbon-oxygen complex J. Coutinho, R. Jones, P.R. Briddon, S. Öberg, L.I. Murin, V.P. Markevich and J.L. Lindström	305
Expanded model for anharmonic vibrational excitation of oxygen in silicon H. Yamada-Kaneta	309

The effect of high temperature-high pressure treatment on the annealing behavior of VO center in neutron-irradiated Czochralski silicon C.A. Londos, M. Potsidou, A. Misiuk, V.V. Emtsev and J.Bak-Misiuk	313
Effect of stress on accumulation of oxygen in silicon implanted with helium and hydrogen A. Misiuk, A. Barcz, V. Raineri, J. Ratajczak, J. Bak-Misiuk, I.V. Antonova, W. Wierzchowski and K. Wieteska	317
Incorporation of oxygen or di-hydrogen in silicon monovacancy: spin-resonance study of defect excited state T. Mchedlidze, N. Fukata and M. Suezawa	321
Thermal donors and radiation-induced defect states in transmutation doped gamma-irradiated silicon S.I. Budzulyak, Yu.P. Dotsenko, V.M. Ermakov, V.V. Kolomoets and E.F. Venger	325
Ab initio study of atomic oxygen adsorption on the Si(111)7 × 7 surface M.J. Caldas, R.J. Baierle, R.B. Capaz and E. Artacho	329
3.4. Erbium	
Defects and their influence on the luminescence of rare-earth ions implanted in single crystal Si N.A. Sobolev	333
Time-resolved investigation of the mid-infrared-induced enhancement of Er ³⁺ emission in Si M. Forcales, I.V. Bradley, J.-P.R. Wells and T. Gregorkiewicz	337
Observation of Zeeman effect in photoluminescence of Er ³⁺ ion imbedded in crystalline silicon N.Q. Vinh, H. Przybylińska, Z.F. Krasil'nik, B.A. Andreev and T. Gregorkiewicz	340
Erbium in SiO _x environment: ways to improve the 1.54 μm emission G. Kocher, H. Przybylinska, M. Stepikhova, L. Palmetshofer and W. Jantsch	344
Excitation of Si:Er with sub-band-gap energies M.A.J. Klik and T. Gregorkiewicz	348
Shallow donors in silicon coimplanted with rare-earth ions and oxygen V.V. Emtsev Jr., C.A.J. Ammerlaan, B.A. Andreev, G.A. Oganessian, D.S. Poloskin and N.A. Sobolev	350
Site-selective excitation of Er ³⁺ ions in oxygen-rich silicon A. Kozanecki, D. Kuritsyn, H. Przybylińska and W. Jantsch	354
Erbium excitation across the bulk of silicon wafer: an effect of p-n junction at Si/Si:Er interface N.Q. Vinh, I.N. Yassievich and T. Gregorkiewicz	357
Electrically active centers in light emitting Si:Er/Si structures grown by the sublimation MBE method V.B. Shmagin, B.A. Andreev, E.N. Morozova, Z.F. Krasil'nik, D.I. Kryzhkov, V.P. Kuznetsov, E.A. Uskova, C.A.J. Ammerlaan and G. Pensl	361
Light emission from erbium doped nanostructures embedded in silicon microcavities N.T. Bagraev, A.D. Bouravleuv, W. Gehlhoff, L.E. Klyachkin, A.M. Malyarenko, M.M. Mezdrogina, V.V. Romanov and A.P. Skvortsov	365
Erbium in Si and GaN: extended versus point defects P.H. Citrin, D.R. Hamann and P.A. Northrup	369
Spectroscopic ellipsometry study of the layer structure and impurity content in Er-doped nanocrystalline silicon thin films M. Losurdo, M.F. Cerqueira, M.V. Stepikhova, E. Alves, M.M. Giangregorio, P. Pinto and J.A. Ferreira	374

Determination of the atomic configuration of Er–O complexes in silicon by the super-cell FLAPW method M. Hashimoto, A. Yanase, H. Harima and H. Katayama-Yoshida	378
Study of Er-related defects in a-Si:H(Er)/c-n-Si heterostructures by thermally activated current spectroscopy J. Vovk, A. Nazarov, V. Lysenko, O. Kon'kov and E. Terukov	382
Spectroscopic characterisation of the erbium impurity in crystalline semiconductors C.A.J. Ammerlaan	387
<i>3.5. Metallic impurities</i>	
Ultra-fast diffusion mechanism of the late 3d transition metal impurities in silicon Y. Kamon, H. Harima, A. Yanase and H. Katayama-Yoshida	391
Nitrogen effect on gold diffusion in Cz Si A.L. Parakhonsky, E.B. Yakimov and D. Yang	396
New electron spin resonance spectra from iron–vacancy pair in silicon: II. Hyperfine interactions and isotopic effect T. Mchedlidze and M. Suezawa	400
Evolution of copper–hydrogen-related defects in silicon S. Knack, J. Weber, H. Lemke and H. Riemann	404
Electronic and atomic structure of transition-metal–hydrogen complexes in silicon P.T. Huy and C.A.J. Ammerlaan	408
Time-resolved photoluminescence study of Si:Ag N.Q. Vinh, M.A.J. Klik and T. Gregorkiewicz	414
Detection of diffusional jumps of interstitial Fe in silicon by Mössbauer spectroscopy H.P. Gunnlaugsson, M. Dietrich, M. Fanciulli, K. Bharuth-Ram, R. Sielemann, G. Weyer and ISOLDE Collaboration	418
New electron spin resonance spectra from iron-vacancy pair in silicon: I. Defect with two values for the spin T. Mchedlidze and M. Suezawa	421
Theoretical study of pressure-induced negative effective U of a tungsten atom in crystalline silicon I. Kitagawa and T. Maruizumi	424
Precipitation-enhanced diffusion of nickel in dislocation-free silicon studied by in-diffusion and annealing processes S. Tanaka, H. Kitagawa and T. Ikari	427
Diffusion of ^{195}Au in amorphous Si_3N_4 and Si_4N_3 T. Voss, S. Matics, A. Strohm, W. Frank, G. Bilger and ISOLDE Collaboration	431
Properties of Cr in hydrogenated Si Y. Sato, T. Takahashi and M. Suezawa	434
Optical absorption spectra of platinum-related defects in silicon N. Fukata, K. Saito and M. Suezawa	438
<i>3.6. Point and extended defects</i>	
Identification of getter defects in high-energy self-implanted silicon at $R_p/2$ R. Krause-Rehberg, F. Börner, F. Redmann, J. Gebauer, R. Kögler, R. Kliemann, W. Skorupa, W. Egger, G. Kögel and W. Triftshäuser	442
Nanoindentation pop-in effect in semiconductors H.S. Leipner, D. Lorenz, A. Zeckzer, H. Lei and P. Grau	446

Mechanical strength of nitrogen-doped silicon single crystal investigated by three-point bending method G. Wang, D. Yang, D. Li, Q. Shui, J. Yang and D. Que	450
Self-interstitial clusters in silicon T.A.G. Eberlein, N. Pinho, R. Jones, B.J. Coomer, J.P. Goss, P.R. Briddon and S. Öberg	454
Self-interstitial-oxygen related defects in low-temperature irradiated Si L.I. Khirunenko, L.I. Murin, J.L. Lindström, M.G. Sosnin and Yu.V. Pomozov	458
Divacancies in proton irradiated silicon: characterization and annealing mechanisms R. Poirier, S. Roorda, F. Schiettekatte, M. Lalancette and J. Zikovsky	462
Do we know the energy levels of radiation defects in silicon? L.F. Makarenko	465
Dopant interaction with a dislocation in silicon: local and non-local effects A. Antonelli, J.F. Justo and A. Fazzio	470
Modeling the subsurface region of Cz-Si wafers with properly fabricated bulk FZ-Si samples T. Mchedlidze, N. Fukata and M. Suezawa	474
High-energy proton radiation induced defects in tin-doped n-type silicon E. Simoen, C. Claeys, V. Privitera, S. Coffa, A.N. Larsen and P. Clauws	477
Interface strain in thermal Si/SiO ₂ analysed by frequency-dependent electron spin resonance D. Pierreux and A. Stesmans	481
C–V and G–V characterization of defects in ultrathin SiO ₂ thermally grown on RF plasma-hydrogenated silicon S. Alexandrova, A. Szekeres and E. Halova	485
Electrically active centers in partial dislocations in semiconductors J.F. Justo and L.V.C. Assali	489
Kinetic Monte Carlo study of dislocation motion in silicon: soliton model and hydrogen enhanced glide S. Scarle, N. Martsinovich, C.P. Ewels and M.I. Heggie	493
Do we really need configuration interaction theory to understand the negative vacancy in silicon? U. Gerstmann, E. Rauls, H. Overhof and Th. Frauenheim	497
Equilibrium concentration of vacancies under the anisotropic stress field around an impurity K. Tanahashi, N. Inoue and Y. Mizokawa	502
<i>3.7. Defect reactions</i>	
Mechanisms of capture- and recombination-enhanced defect reactions in semiconductors Y. Shinozuka	506
Dynamics of Si self-interstitial clustering using the fast-diffusing I ₃ cluster M. Gharaibeh, S.K. Estreicher and P.A. Fedders	510
Defect reactions associated with the dissociation of the phosphorus–vacancy pair in silicon V.P. Markevich, O. Andersen, I.F. Medvedeva, J.H. Evans-Freeman, I.D. Hawkins, L.I. Murin, L. Dobaczewski and A.R. Peaker	513

4. Germanium

- Enhanced oxygen dimer and thermal donor formation in irradiated germanium studied by local vibrational mode spectroscopy
P. Vanmeerbeek, P. Clauws and W. Mondelaers 517
- Correlated to random transition of ionized impurity distribution in n-type Ge:(As, Ga)
J. Kato, K.M. Itoh and E.E. Haller 521
- Ion-implantation and diffusion behaviour of boron in germanium
S. Uppal, A.F.W. Willoughby, J.M. Bonar, A.G.R. Evans, N.E.B. Cower, R. Morris and M.G. Dowsett 525
- Vacancies and self-interstitials in germanium: a picture derived from radioactive probes
R. Sielemann, H. Hässlein, Ch. Zistl, M. Müller, L. Stadler and V.V. Emtsev 529

5. SiGe alloys

- The interstitial boron and the boron-germanium complex in silicon-germanium crystals
J. Hattendorf, W.-D. Zeitz, N.V. Abrosimov and W. Schröder 535
- Interstitial oxygen in GeSi alloys
I. Yonenaga, M. Nonaka and N. Fukata 539
- Self-diffusion of ^{71}Ge in Si-Ge
A. Strohm, T. Voss, W. Frank, J. Räisänen and M. Dietrich 542
- Low temperature muonium behaviour in Cz-Si and Cz-Si_{0.91}Ge_{0.09}
P.J.C. King and I. Yonenaga 546
- Interaction of divacancies with Ge atoms in Si_{1-x}Ge_x
L. Khirunenko, Yu. Pomozov, M. Sosnin, N. Abrosimov and W. Schröder 550
- High resolution minority carrier transient spectroscopy of defects in Si and Si/SiGe quantum wells
J.H. Evans-Freeman and M.A. Gad 554
- Alloy fluctuations in Si_{1-x}Ge_x crystals
G. Kocher, W. Jantsch, N. Abrosimov, S. Egorov, A. Zabrodskii, B. Andreev and H.G. Grimmeiss 558

6. Diamond

- The new assignment of hyperfine parameters for deep defects in diamond
U. Gerstmann and H. Overhof 561
- Transition metals in diamond: Do chemical trends arise from ab initio calculations?
K. Johnston and A. Mainwood 565
- Annealing of monovacancies in electron and γ -irradiated diamonds
S. Dannefaer, A. Pu, V. Avalos and D. Kerr 569
- Defect-induced graphitisation in diamond implanted with light ions
A.A. Gippius, R.A. Khmel'nitsky, V.A. Dravin and A.V. Khomich 573

Modelling electron energy-loss spectra of dislocations in silicon and diamond C.J. Fall, J.P.G. Goss, R. Jones, P.R. Briddon, A.T. Blumenau and T. Frauenheim	577
The variation of optical absorption of CVD diamond as a function of temperature C. Piccirillo, G. Davies, A. Mainwood and C.M. Penchina	581
Photoelectrical properties of the 1.682-eV and 3 H centres in diamond K. Iakoubovskii and A. Stesmans	585
Photo-EPR studies on the AB ₃ and AB ₄ nickel-related defects in diamond R.N. Pereira, W. Gehlhoff, N.A. Sobolev, A.J. Neves and D. Bimberg	589
Electrically detected magnetic resonance studies of phosphorus doped diamond T. Graf, M.S. Brandt, C.E. Nebel, M. Stutzmann and S. Koizumi	593
High-temperature high-pressure annealing of diamond Small-angle X-ray scattering and optical study A.A. Shiryayev, M.T. Hutchison, K.A. Dembo, A.T. Dembo, K. Iakoubovskii, Yu.A. Klyuev and A.M. Naletov	598
Volume expansion and stress tensors for self-interstitial aggregates in diamond J.P. Goss, R. Jones and P.R. Briddon	604
Modeling fluorescence of single nitrogen-vacancy defect centers in diamond A.P. Nizovtsev, S.Ya. Kilin, C. Tietz, F. Jelezko and J. Wrachtrup	608
Irradiation effects in semiconducting diamonds N. Kristianpoller, D. Weiss and R. Chen	612
Nickel related defects in diamond: the 2.51 eV band M.H. Nazaré, J.C. Lopes and A.J. Neves	616
7. Silicon carbide	
<i>7.1. Intrinsic and extended defects</i>	
Positively charged carbon vacancy in 6H-SiC: EPR study V.Ya. Bratus, I.N. Makeeva, S.M. Okulov, T.L. Petrenko, T.T. Petrenko and H.J. von Bardeleben	621
The annealing product of the silicon vacancy in 6H-SiC Th. Lingner, S. Greulich-Weber, J.M. Spaeth, U. Gerstmann, E. Rauls and H. Overhof	625
Illumination effects in irradiated 6H n-type SiC observed by positron annihilation spectroscopy F. Redmann, A. Kawasuso, K. Petters, H. Itoh and R. Krause-Rehberg	629
Formation and annihilation of intrinsic-related defect centers in high energy electron-irradiated or ion-implanted 4H- and 6H-silicon carbide M. Weidner, T. Frank, G. Pensl, A. Kawasuso, H. Itoh and R. Krause-Rehberg	633
Calculation of hyperfine parameters of positively charged carbon vacancy in SiC T.T. Petrenko, T.L. Petrenko, V.Ya. Bratus and J.L. Monge	637
DLTS study of defects in 6H- and 4H-SiC created by proton irradiation D.V. Davydov, A.A. Lebedev, V.V. Kozlovski, N.S. Savkina and A.M. Strel'chuk	641

Interstitial-based vacancy annealing in 4H-SiC E. Rauls, T.E.M. Staab, Z. Hajnal and Th. Frauenheim	645
The ground state of silicon vacancies in 6H-SiC and 15R-SiC Th. Lingner, S. Greulich-Weber and J.-M. Spaeth	649
Positron annihilation study of vacancy-type defects in silicon carbide co-implanted with aluminum and carbon ions T. Ohshima, A. Uedono, H. Abe, Z.Q. Chen, H. Itoh, M. Yoshikawa, K. Abe, O. Eryu and K. Nakashima	652
Interstitials in SiC: a model for the D_{II} center A. Mattausch, M. Bockstedte and O. Pankratov	656
Vacancies in He-implanted 4H and 6H SiC epilayers studied by positron annihilation A. Kawasuso, M. Weidner, F. Redmann, T. Frank, P. Sperr, R. Krause-Rehberg, W. Triftshäuser and G. Pensl	660
Vacancy type defects in Al implanted 4H-SiC studied by positron annihilation spectroscopy J. Slotte, K. Saarinen, A.Yu. Kuznetsov and A. Hallén	664
Negatively charged vacancy defects in 6H-SiC after low-energy proton implantation and annealing M.-F. Barthe, D.T. Britton, C. Corbel, A. Hempel, L. Henry, P. Desgardin, W. Bauer-Kugelmann, G. Kögel, P. Sperr and W. Triftshäuser	668
Electron paramagnetic resonance studies of a carbon vacancy-related defect in as-grown 4H-SiC V.V. Kononov, M.E. Zvanut, V.F. Tsvetkov, J.R. Jenny, St.G. Müller and H.McD. Hobgood	671
Defects in 4H silicon carbide J.P. Bergman, L. Storasta, F.H.C. Carlsson, S. Sridhara, B. Magnusson and E. Janze'n	675
Neutral and negatively charged silicon vacancies in neutron irradiated SiC: a high-field electron paramagnetic resonance study P.G. Baranov, E.N. Mokhov, S.B. Orlinskii and J. Schmidt	680
Detection of defects in SiC crystalline films by Raman scattering S. Nakashima, Y. Nakatake, Y. Ishida, T. Talkahashi and H. Okumura	684
<i>7.2. Impurities</i>	
Electrical and optical properties of erbium-related centers in 6H silicon carbide O. Klettke, S.A. Reshanov, G. Pensl, Y. Shishkin, R.P. Devaty and W.J. Choyke	687
Contactless studies of semi-insulating 4H-SiC W.E. Carlos, W.J. Moore, G.C.B. Braga, J.A. Freitas Jr., E.R. Glaser and B.V. Shanabrook	691
Influence of annealing temperature upon deep levels in 6H SiC F. Perjeru, R.L. Woodin and M.E. Kordesch	695
EPR and photoluminescence studies of semi-insulating 4H-SiC samples E.N. Kalabukhova, S.N. Lukin, W.C. Mitchel, A. Saxler and R.L. Jones	698
Defect correlated emission and electrical properties of 4H- and 6H-SiC epitaxial layers doped by nuclear transmutation doping (NTD) H. Heissenstein, H. Sadowski and R. Helbig	702

Characterization of deep centers in bulk n-type 4H-SiC Z.-Q. Fang, D.C. Look, A. Saxler and W.C. Mitchel	706
Photoluminescence study of beryllium implantation induced intrinsic defects in 6H-silicon carbide S. Fung, X.D. Chen, C.D. Beling, Y. Huang, Q. Li, S.J. Xu, M. Gong, T. Henkel, H. Tanoue and N. Kobayashi	710
Luminescence characterization of titanium related defects in 6H-SiC Yu.M. Suleimanov, I. Zaharchenko and S. Ostapenko	714
Beryllium implantation induced deep levels in 6H-silicon carbide X.D. Chen, S. Fung, C.D. Beling, M. Gong, T. Henkel, H. Tanoue and N. Kobayashi	718
Passivation of p-type dopants in 4H-SiC by hydrogen B. Aradi, A. Gali, P. Deák, N.T. Son and E. Janzén	722
First-principles studies of Ti impurities in SiC K.O. Barbosa, V.V.M. Machado and L.V.C. Assali	726
Deep level defects in sublimation-grown 6H silicon carbide investigated by DLTS and EPR K. Irmischer, I. Pintilie, L. Pintilie and D. Schulz	730
Diffusion of boron in silicon carbide K. Rüschenschmidt, H. Bracht, M. Laube, N.A. Stolwijk and G. Pensl	734
 8. GaAs and AlGaAs	
<i>8.1. Point and extended defects</i>	
Identification of arsenic antisite defects with EL2 by nanospectroscopic studies of individual centers A. Hida, Y. Mera and K. Maeda	738
Study of As self-diffusion in GaAs using sulfur as a tracer N. Engler, H.S. Leipner, R.F. Scholz, P. Werner and U. Gösele	742
On the microscopic structure of the EL6 defect in GaAs Th. Steinegger, B. Gründig-Wendrock, M. Jurisch and J.R. Niklas	745
Magneto-optical and ODEPR investigations of native defects in substrate-free LT-MBE grown GaAs I. Tkach, K. Krambrock, C. Steen, P. Kiesel and J.-M. Spaeth	749
On the problem of the EL2 structure in semi-insulating GaAs: high-frequency ODEPR/ODENDOR measurements in W-band I. Tkach, K. Krambrock and J.-M. Spaeth	753
Capture kinetics at deep-level defects in lattice-mismatched GaAs-based heterostructures O. Yastrubchak, T. Wosiński, A. Mąkosa, T. Figielski and A.L. Tóth	757
Passivation of growth defects in GaAs/AlGaAs multiple quantum well structures by CF ₄ plasma T.S. Shamirzaev, K.S. Zhuravlev, A.Yu. Kobitski, H.P. Wagner and D.R.T. Zahn	761
Exciton localization dynamics due to intrinsic interface defects within growth island terraces of all-binary GaAs/AlAs quantum wells K. Fujiwara and K.H. Ploog	765

Metastable irradiation induced defects in Be doped $\text{Al}_{0.5}\text{Ga}_{0.5}\text{As}$ MBE layers J. Szatkowski, E. Placzek-Popko, A. Hajdusianek, A. Johansen and C. Soerensen	769
Raman probing of the wave function of collective excitations in the presence of disorder Yu.A. Pusep, S.S. Sokolov, W. Fortunato, J.C. Galzerani and J.R. Leite	772
Deep-level transient spectroscopy study of electron traps in rapid thermally annealed SiO_2 -capped n-type GaAs layers grown by metalorganic chemical vapour deposition P.N.K. Deenapanray, M. Lay, D. Åberg, H.H. Tan, B.G. Svensson, F.D. Auret and C. Jagadish	776
<i>8.2. Impurities</i>	
Acceptor-hydrogen complexes in semiconductors under pressure M.D. McCluskey, K.K. Zhuravlev, B.R. Davidson and R.C. Newman	780
Donor-acceptor recombination in δ -doped type II GaAs/AlAs superlattices D.V. Gulyaev, A.M. Gilinsky, A.I. Toropov, A.K. Bakarov and K.S. Zhuravlev	784
The DX^- -centre formation at high electric fields in planar-doped GaAs:Si M. Asche and O.G. Sarbey	788
Study of vacancy-type defects after Cu diffusion in GaAs V. Bondarenko, K. Petters, R. Krause-Rehberg, J. Gebauer and H.S. Leipner	792
Luminescence properties of Dy-doped GaAs grown by organometallic vapor phase epitaxy Y. Fujiwara, T. Koide, S. Jinno, Y. Isogai and Y. Takeda	796
Investigation of Cu-related deep levels in semi-insulating GaAs by PICTS G. Zychowitz, W. Siegel, T. Steinegger, G. Kühnel and J.-R. Niklas	800
The effect of Si site-switching in GaAs on electrical properties and potential fluctuation H.G. Svavarsson, J.T. Gudmundsson, G.I. Gudjonsson and H.P. Gislason	804
Incorporation and thermal stability of defects in highly p-conductive non-stoichiometric GaAs:Be P. Specht, M.J. Cich, R. Zhao, J. Gebauer, M. Luysberg and E.R. Weber	808
Native point defects in non-stoichiometric GaAs doped with beryllium J. Gebauer, R. Zhao, P. Specht, F. Börner, F. Redmann, R. Krause-Rehberg and E.R. Weber	812
Rhodium-related deep levels in n-type MOCVD GaAs M. Zafar Iqbal, A. Majid, S. Haidar Khan, A. Ali, N. Zafar, A. Dadgar and D. Bimberg	816
Stress-induced transformation of defects in homoepitaxial beryllium-doped GaAs thin films J. Bak-Misiuk, A. Misiuk, K.S. Zhuravlev, J.Z. Domagala, J. Adamczewska and V.V. Preobrazhenskii	820
Carbon incorporation during growth of GaAs at low temperatures J. Herfort, W. Ulrici, M. Moreno, M. Luysberg and K.H. Ploog	823
Study of depth distribution of metastable hydrogen-related defects in n-type GaAs O.A. Soltanovich, E.B. Yakimov, V.A. Kagadei and L.M. Romas	827
Zinc diffusion enhanced Ga diffusion in GaAs isotope heterostructures H. Bracht, M.S. Norseng, E.E. Haller and K. Eberl	831
Vibrational modes of a hydrogen-impurity centre in LEC-GaAs W. Ulrici and M. Jurisch	835

Nitrogen solubility and N-induced defect complexes in epitaxial GaAs:N S.B. Zhang and S.-H. Wei	839
Plasmon-like oscillations of the electrons localized by the DX centers in doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ Yu.A. Pusep, A.J. Chiquito, W. Fortunato and J.C. Galzerani	843
9. Other III-V compounds	
Defect engineering in III-V ternary alloys: effects of strain and local charge on the formation of substitutional and interstitial native defects A.A. Bonapasta and P. Giannozzi	846
Interplay of nitrogen and hydrogen in $\text{In}_x\text{Ga}_{1-x}\text{As}_{1-y}\text{N}_y/\text{GaAs}$ heterostructures A. Polimeni, G.B.H. von Högersthal, M. Bissiri, V. Gaspari, F. Ranalli, M. Capizzi, A. Frova, A. Miriametro, M. Geddo, M. Fischer, M. Reinhardt and A. Forchel	850
Mechanism of zinc diffusion in gallium antimonide S.P. Nicols, H. Bracht, M. Benamara, Z. Liliental-Weber and E.E. Haller	854
Carbon-doped MOCVD InP is semi-insulating up to 700°C R.C. Newman, B.R. Davidson, J. Wagner, M.J.L. Sangster and R.S. Leigh	858
Motional properties of positive muonium in gallium III-V compounds R.L. Lichti, K.H. Chow, B. Hitti, E.A. Davis, S.K.L. Sjøe and S.F.J. Cox	862
Substitutional incorporation of arsenic from GaAs substrates into MOVPE grown InSbBi thin films M.C. Wagener, J.R. Botha and A.W.R. Leitch	866

Abstract

Ab initio molecular-dynamics (MD) simulations are increasingly being used to study defects in silicon. Simulated quenching and/or conjugate gradient calculations are now common tools to explore the minima of complicated potential energy surfaces. However, the real dynamics are in the constant-temperature runs. These highly computer-intensive simulations are still limited to real times of the order of picoseconds. However, they provide a fantastic window into processes that are beyond the reach of static ($T = 0$ K) calculations. In this paper, the challenges of constant-temperature ab initio MD simulations are discussed and examples given: the formation of H_2^* , the diffusion of small self-interstitial clusters, the restless interstitial H_2 molecule, and the dynamic calculation of vibrational frequencies from the velocity–velocity autocorrelation function. The results are obtained using methods based on Sankey's 'ab initio tight-binding' approach, with atomic-like basis sets rather than plane waves. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Molecular-dynamics; Silicon; Hydrogen; Self-interstitials

1. Introduction

This paper discusses the use of ab initio molecular-dynamic (MD) simulations in constant-temperature mode to study the dynamic behavior of point defects in crystalline silicon. 'Ab initio' refers to the way in which the electronic problem is solved, and implies that the method contains no parameters fitted to experimental data. This avoids the transferability problems that are often associated with the use of semiempirical parameters. However, these calculations do involve approximations and user inputs. Density-functional theory is used to solve the electronic problem within the local-density or generalized-gradient approximations. The theorist chooses the basis set type (plane waves or local basis) and size. The core electrons are hidden by ab initio pseudopotentials. Periodic supercells of finite size approximate the host crystal: 64 host atoms cells have been the norm, but 128 or 216 cells are

becoming common. The k -point sampling is often reduced to just one point, although larger samplings are needed and are increasingly used. On a more fundamental level, the electronic excited states are ignored as are the nuclear quantum effects such as zero-point energies, tunneling, quantum rotational states, or nuclear spins.

Yet, the predictive power of ab initio theory has dramatically improved over the past decade. Quantities such as defect geometries, energetics (binding and formation energies, activation energies for diffusion, etc.) and vibrational properties are now predicted quite reliably in many cases. Typical accuracies for local vibrational modes (LVMs) are of the order of 5–8%, which still means 100 cm^{-1} or more for H-related complexes. Other quantities notoriously difficult to calculate include DLTS levels and photoluminescence bands. Processes that involve more than one charge state are also very tricky. These include recombination-enhanced and Bourgoin–Corbett diffusion processes.

Beyond the calculation of observable properties, an important purpose of theory is to provide information on defects and processes that are not observable. The

E-mail address: stefan.estreicher@ttu.edu (S.K. Estreicher).

properties of the isolated self-interstitial are only known through theory. There are numerous examples of 'simple' initial situations which result in complex final structures following an anneal or implant, and precious little experimental information can be obtained about the occurrences during the energetic treatment. Examples include the formation of oxygen-related thermal donors (with or without H enhancement) or of {311} self-interstitial platelets.

One step beyond ab initio static methods is the inclusion of nuclear (or rather, ionic: nucleus+core electrons), kinetic energy. The simplest way to achieve this is to remain within the Born–Oppenheimer approximation and treat the ions as classical point masses that obey Newton's laws of motion and are decoupled from the electronic problem. In semiconductors such as Si that have band gaps of the order of thousands of degrees, the electrons are left in their ground state (zero electronic temperature) and the temperature of the sample is determined by the ionic kinetic energy. The explicit inclusion of nuclear quantum mechanics within a dynamic scheme is still some years in the future as concerning point defects in semiconductors. Extensive quantum treatments will ultimately be required to understand some features of impurities such as H and its light isotope muonium. The quantum effects associated with heavier ions, say O or Si, are less important.

The inclusion of classical dynamics in constant-temperature mode opens up a whole new world in the study of point defects in semiconductors. This became obvious when the diffusion of a proton was first calculated [1] in 1989 using ab initio MD simulations. Since then, MD simulations have become a household name, even though most authors use such simulations in *static* mode, using conjugate gradients to explore complicated energy surfaces and discuss the properties of a system at a local minimum of the potential energy. There have been far fewer *dynamic* (constant-temperature) studies of defects. This paper deals with dynamic studies, the problems associated with them, and with examples of results that cannot be extracted from static calculations. The examples are (1) *defect reactions*, the formation of the H_2^+ complex, (2) *defect diffusion*, the diffusion of small self-interstitial clusters, (3) *the restless H_2* , an interstitial molecule which bounces within its tetrahedral cage even at low temperatures, and (4) *the dynamic calculation of LVMs* from the velocity–velocity autocorrelation function. This paper is not a review of the field. Numerous authors are developing or using ab initio (and semiempirical) MD codes in order to discover the dynamics of defects, in the bulk and on surfaces. A review of MD simulations has been recently published (for a recent review, see Ref. [2]) and several excellent monographs are available (See, e.g. Refs. [3,4]).

2. Classical MD simulations

As mentioned above, the idea behind classical MD simulations is simple. Assuming the Born–Oppenheimer approximation, one separates the electronic from the ionic problem. The ions are classical objects and the temperature of the system is related to their kinetic energy. The electrons are treated quantum-mechanically in their ground state. The total energy is calculated at a time t . Its gradient gives the force on each ion and Newton's laws of motion are solved to obtain their positions and velocities at the time $t + \Delta t$. Each ion is moved to its new position, assigned its new velocity and the electronic problem is solved again. One can simulate annealing or quenching by adding or removing a fraction of the kinetic energy every few time steps, or force the convergence towards a minimum of the potential energy (at 0 K) using conjugate gradients. In this case, it is desirable to use a large cell, a converged basis set, and more than one k point in order to describe the equilibrium properties as accurately as possible.

The time step Δt must be chosen carefully. In the case of the interstitial H_2 molecule in Si, the H–H stretch mode is around 3600 cm^{-1} , which is about 10^{14} Hz . A complete oscillation takes place every 10 fs or so. In order to describe the motion of the proton, 30–50 time steps are needed per oscillation, which implies that Δt is of the order of 0.2 fs. For heavier (and therefore slower) ions such as Si, 2.0 fs can be used. A rapid quench or a conjugate gradient calculation typically involves a few hundred time steps in order to reduce the largest force component below 0.03 eV/\AA or so.

Constant-temperature simulations imply substantial computer effort. With $\Delta t = 1.0\text{ fs}$, one thousand time steps is only one ps real time! Many thousands of time steps are required in order to do meaningful dynamics and even then, there is no certainty that anything at all will happen. The dynamics of interest include defect reactions or diffusion which are basically chemical reactions. Once a reaction begins, it occurs in a very short time. The killers are the attempt frequency and activation energy. In order for an Si–H bond to break or for O_i to jump for one bond-centered (BC) site to another, one must wait for all the neighboring host atoms to be at the precisely 'right' place and move with the 'right' velocity. Then, everything happens very quickly. The trick is in looking exactly at the right time. This may be tricky to set up, since the dynamics are rarely what one expects them to be.

In order to maximize the probability of success, one begins with the smallest realistic cell, basis set, and number of k points, assigns some high temperature, runs as many time steps as possible, and prays a lot. A healthy amount of experience and luck do help. However, if some interesting dynamics does happen, one knows better what to expect and how to prepare runs at

lower temperatures with larger cells and/or basis sets. In many cases, however, nothing happens and one has wasted a lot of CPU time. We can dream of a novel computer that would be 1000 times faster. Then, one could simulate a few nanoseconds, and/or increase the cell size to a few thousand atoms, and/or sample more k points, but probably not all these parameters can be varied simultaneously. For the foreseeable future, the art of constant-temperature dynamics will remain the art of compromise.

The computer outputs include the position and velocity of every ion in the system at every time step. This can be turned into movies which are comparable to an incredible ‘theoretical microscope’ with atomic resolution in space and femtosecond resolution in time [5]. Movies are very visual and therefore very convincing. One must constantly remind oneself that only the tiniest window in time is seen. Indeed, the longest *ab initio* simulations done to date span a few tens of picoseconds, hardly enough to reach equilibrium or steady state. Further, this is theory, *ab initio* yes, but theory nonetheless, which includes all the approximations listed above.

We use the SIESTA [6,7] code in our calculations. It is a first-principles self-consistent density-functional method with all the usual features of first-principles density-functional codes. The basis sets for the electronic states consist of numerical linear combinations of atomic orbitals of the Sankey type [8,9] rather than plane waves. These basis sets are flexible, ranging here from minimal (single-zeta, SZ) to double-zeta with polarization functions (DZP).

3. Examples

The four examples below, all in Si, illustrate situations, which would be either very difficult or outright impossible to describe using static methods. The first deals with the radiation-induced transition of interstitial H_2 into the H_2^* complex. This result involves the interactions between native defects and an interstitial impurity. The second is the surprisingly fast diffusion of small self-interstitial clusters. This counter-intuitive result shows that small aggregates may diffuse through a crystal much faster than the dissociated species. The third example involves the interstitial H_2 molecule, which moves rapidly within its tetrahedral interstitial cage and bounces off its ‘walls’, thus exchanging energy with the host crystal. The fourth and the last example deals with the calculation of LVMs at finite temperature using the velocity–velocity autocorrelation function.

3.1. A mechanism for H_2^* formation

The two simplest hydrogen dimers in Si are the interstitial H_2 molecule and the H_2^* complex. The

Fig. 1. The H_2^* complex forms when a vacancy and a self-interstitial recombine near interstitial H_2 .

molecule is common in samples grown in a hydrogen ambient or exposed to such an ambient near the melting point then quenched, as well as in plasma-etched samples. Interstitial H_2 gives rise to a tiny Raman [10] and infra-red [11] line. However, irradiation renders this ‘hidden’ hydrogen very visible indeed [12]. In particular, the H_2^* complex always appears in irradiated samples. This dimer, shown in Fig. 1, has one Si–Si bond replaced by two Si–H bonds along the same trigonal axis, one H near the BC site and the second in an antibonding (AB) configuration. This complex has been predicted some years ago by Deak et al. [13] and Chang et al. [14], then identified by IR spectroscopy by Holbech et al. [15]. It anneals above 200°C.

We studied the interactions between interstitial H_2 molecules and a nearby vacancy or self-interstitial [16]. MD simulations at 1000 K show that the molecules dissociate very quickly and the result is either the partially saturated vacancy {V,H,H} or a self-interstitial complex with two Hs {I,H,H}. Similarly, H_2 melts when placed inside a larger void, the ring-hexavacancy [17]. Molecular H_2 cannot survive inside an unpassivated internal void in Si.

Ron Newman suggested that the {V,H,H} or {I,H,H} complexes might further react with I or V, respectively, effectively resulting in vacancy-interstitial recombination at H_2 . We were successful with the reaction {I,H,H} + V → H_2^* , which is the more energetic of the

two possible reactions [18]. Starting with a vacancy and the {I,H,H} complex in the same 64-Si atoms cell (quenched to make sure that the simulation begins at a local minimum of the potential energy), we raised the temperature to 1000 K and let go for 8000 time steps. The calculation was not performed using SIESTA, but a Harris-functional version of the Sankey code. The reaction occurred with the Hs first forming two Si–H bonds along different trigonal axes. A single H jump resulted in H_2^* at the very end of the simulation [5].

3.2. The diffusion of small self-interstitial clusters

Large concentrations of self-interstitials (Is) are generated during energetic processes such as ion implantation. The isolated I has never been detected experimentally. However, Is precipitate and form large platelets in {311} planes which become reservoirs of Is later involved in the transient-enhanced diffusion of the B acceptor [19]. A number of theorists have studied the stable structures of small I_n clusters and various precipitation mechanisms (See Ref. [20] and references therein) involving $I + I + I + \dots \rightarrow I_n$. From the systematic geometry optimizations, we obtained a series of stable and metastable configurations of self-interstitial clusters I_n , with $n = 1, 2, 3$, and 4. Our most stable geometry [21] for the tri-interstitial, I_3^a , is an equilateral triangle centered at a BC site. It involves the substantial relaxation of only two host atoms, the two nearest-neighbors (NNs) on either side of the I_3^a triangle (Fig. 2, top). An alternative configuration, which we label I_3^b (Fig. 2, bottom), was proposed by Coomer et al. [22] as the complex responsible for the W photoluminescence band. It consists of an identical equilateral triangle in the {111} plane. However, it shifts and involves three adjacent BC sites and thus requires six host atoms to relax substantially. Although there is now an agreement [23] that I_3^a is more stable than I_3^b , constant-temperature MD simulations [24] show that both complexes exhibit unexpected dynamic behavior, even at low temperatures.

In the case of I_3^b , the three self-interstitials easily exchange sites, thus continuously turning around the trigonal axis. The stable I_3^a complex diffuses extremely fast as its center of mass (CM) shifts from BC to BC site at the picosecond time scale. This occurs at 1000 K in the 64-host atoms cell with an SZ basis set as well as in the 128-host atoms cell with a DZP set. It also occurs, albeit more slowly, with simulation temperatures as low as 77 K. It is unusual to see dynamics at 77 K at the ps time scale. Although no reliable diffusivity should be extracted from a handful of diffusion jumps, it is tempting to derive an order of magnitude. From our longest simulation (1000 K, 64-cell, SZ basis), we get a huge number, just under $10^4 \text{ cm}^2/\text{s}$. There are two other I_n clusters which diffuse at the picoseconds time scale at 1000 K. Both of them also involve a single BC site in

Fig. 2. Side and top (along $\langle 111 \rangle$, top) views of the tri-interstitial clusters. The stable configuration (I_3^a , top), an equilateral triangle centered at a single BC site diffuses very fast even at low temperatures. The metastable configuration (I_3^b , bottom) involves three adjacent BC sites. At $T > 0 \text{ K}$, the three Is exchange positions around the trigonal axis, but the center of mass remains in place.

their stable configuration. They are I_2 and one (of twelve) configurations of I_4 .

In all cases, the diffusion mechanism is the same. The Is in these complexes all aim at exchanging site with one of the two host atoms nearest to the BC site. These two atoms are already displaced from their ideal substitutional sites and are being pushed by two, three, or even four Is. Thus, several Is join forces in expelling one host atom. As soon as this occurs, the other members of the complex only need to rearrange the entire complex to become centered at a BC site adjacent to the original one.

We also looked at the possibility that the fast-diffusing I_3 clusters interact with each other and precipitate. Such a precipitation takes place at a substantial gain in energy when two (or more) I_3^a 's diffuse toward each other along specific lattice directions [20], suggesting that the building blocks of extended structures could be the fast-diffusing I_n complexes described above rather than an isolated I.

3.3. The restless interstitial H_2

The third example involves the interstitial H_2 molecule in Si. This impurity exhibits unexpected features

(for a discussion and references, see Refs. [25,26]). The observed stretch mode is some 550 cm^{-1} lower than the free molecule. The mode is Raman and IR active, and shows no hint of ortho/para splitting. A single HD line is seen, and its frequency is much higher and its amplitude much smaller than expected. Further, uniaxial stress experiments imply that H_2 and D_2 have C_1 symmetry, and that the piezospectroscopic tensors of H_2 and D_2 are identical. Static calculations fail to explain most of these data.

Constant-temperature MD simulations of interstitial H_2 in Si at 77 K show that the molecule continuously moves around the tetrahedral site and bounces off the walls of its cage, thus exchanging energy with its host. The average position of the CM of H_2 moves away from the T site along the $\langle 100 \rangle$ direction as the temperature increases and H_2 visits anharmonic regions of the potential. Further, the CM moves slightly off the $\langle 100 \rangle$ axis under uniaxial stress. The rapid motion of the molecule may also have something to do with the absence of ortho/para splitting [25,26].

3.4. Dynamic calculations of vibrational frequencies

The last example deals with the calculation of vibrational frequencies. The prediction of LVMs for light impurities such as H provides an important link between theory and experiment. The simplest way to estimate frequencies is to calculate total energies at 0 K for a cell relaxed close enough to equilibrium so that a maximum force component in the entire system is of the order of 0.01 eV/\AA . Then, an atom is physically displaced by small amounts $\pm d$ along a specific direction and the frequency of this atom along this direction is extracted from the curvature of the potential energy. In the case of an Si–H stretch mode for example, this would involve displacing H along the Si–H direction. One can either keep the rest of the cell (or cluster) fixed following the displacement of one atom (which underestimates the reaction of the host crystal) or allow the atoms to relax (which overestimates this reaction).

There is no accepted standard for how large the displacement d should be. Quantum chemists typically use 0.01 \AA but in the ‘defect community’, displacements of the order of 0.05 \AA have been used. This issue can be overcome by calculating the total energy for several displacements $\pm d_1, \pm d_2, \dots$ then fitting the potential energy to a polynomial of degree higher than 2. Given a sufficient computer time, this process can be repeated along the three Cartesian directions for all the atoms in the cell, thus allowing the calculation of the entire dynamical matrix. Such methods have been used by a number of authors (for references, see [27]) to calculate LVMs with typical accuracies of the order of 5–8% relative to experimental values.

A recently developed alternative is to use density-functional perturbation theory. The idea is to calculate the dynamical matrix elements analytically from the derivative of the density matrix of the relaxed cell relative to the nuclear displacements, thus setting $d = \delta R_\alpha$, an infinitesimal displacement of nucleus α . This allows the calculation of the entire dynamical matrix, including all the phonons and LVMs, within a purely harmonic approach [27]. Typical frequencies are within 1–5% of the experimental data.

However, actual measurements are done at non-zero temperatures and include the dynamics of the system, such as the coupling of LVMs to phonons, for example. One can extract vibrational frequencies dynamically within constant-temperature MD simulations from the Fourier transform of the velocity–velocity autocorrelation function [3,4,26]. This involves evaluating the integral of the scalar product of velocities at times t and $t + \tau$. In order to obtain good statistics, long simulation times are required. Since the simulations can be done at any desired temperature, LVMs can be obtained as a function of T . In principle, one could extract the entire dynamical matrix from autocorrelation functions but in practice, this requires considerable amount of computer time.

At present, we can only share preliminary results. The full testing of how the frequencies vary with cell-size, basis set and other parameters is under way. We calculated the stretch frequencies of H_2 , HD, and D_2 both in the gas phase and in Si. The calculations involved 12,000 time steps at $T = 30\text{ K}$, with a DZP basis set for H or D and an SZ basis set for the Si atoms. Fig. 3 shows the calculated frequencies for H_2 , HD, and D_2 in Si and in free space. The experimental data are shown as small lines for comparison.

For the free molecules, the measured values in the gas phase are 4161 , 3632 , and 2994 cm^{-1} , respectively. The calculated H_2 line is too low by 0.6% (25 cm^{-1}), HD by 0.1% (5 cm^{-1}) and D_2 by 1.2% (37 cm^{-1}). The agreement is extremely good.

For the molecules in Si, the D_2 , HD, and H_2 lines calculated at 30 K differ from the IR data at 10 K by $+6$, -4 , and 138 cm^{-1} (!), respectively. The first two frequencies are surprisingly similar to the measured values, but the third one is totally out of line. Preliminary results with different basis sets show that the lines do shift, but the errors relative to experiment for D_2 and HD are similar, while that for H_2 is different. At this point, we cannot rule out that some theoretical factor is to be blamed. Maybe the time step is too long or the basis set not converged. However, these parameters work well for free H_2 . There is another possibility. Maybe the classical H_2 molecule in Si should have a frequency higher than the one observed (more in line with the free H_2 value) and some quantum behavior is to be blamed for the lower observed frequency? The

Fig. 3. Stretch frequencies of interstitial D_2 , HD, and H_2 in Si (2649, 3261, and 3739 cm^{-1} , respectively) calculated from the Fourier transform of the velocity-velocity autocorrelation function at 30 K (12,000 time steps) in the 64-Si cell with an SZ basis on Si and a DZP basis on H (or D). Compared to IR measurements at 10 K, D_2 is 6 cm^{-1} too high, HD 4 cm^{-1} too low, and H_2 138 cm^{-1} (!) too high. In contrast, the calculated frequencies of the free molecules are all close to the gas-phase Raman data.

heavier D_2 and HD might not exhibit this quantum behavior. This would imply that it is not the HD line that is too high but the H_2 line that is too low. Indeed, the calculated (classical) frequencies have HD with an anharmonicity much closer to the expected one, about 60 cm^{-1} [28]. A quantum behavior for H_2 could also have something to do with the piezospectroscopic tensors of H_2 and D_2 [29,30].

4. Discussion

Theory as a tool in the study of defects in semiconductors has evolved from methods capable of performing geometry optimizations using semiempirical techniques in small clusters, to ab initio Hartree-Fock and density-functional theory in larger cluster or periodic supercells, to the inclusion of classical dynamics within an ab initio scheme. Despite the fact that numerous approximations remain, the predictive power of theory for geometries, energetics, vibrational frequencies, and a few other measurable quantities has improved dramatically. The examples discussed in this paper illustrate how constant-temperature MD simulations provide new and unexpected insights into the behavior of defects. If such a simulation is successful, one often sees processes occurring in a way more elegant or complicated than intuition suggests. Constant-temperature MD simulations are highly computer-intensive, but this is one problem that technological progress will likely alleviate with time. We have little doubt that much more remains to be acquired from this window into the fascinating dynamics of impurities and defects in semiconductors.

Abstract

Three experiments appear to cast doubt on self-interstitial-free models of the family of thermal donors, based on oxygen defects of increasing size. These are (a) the rapid transformation of $\text{TDD}(N)$ into $\text{TDD}(N+1)$ with activation energies considerably lower than that of oxygen diffusion, (b) the lack of any appreciable spin-density on oxygen in $\text{TDD}(N)^+$, and (c) the observation of only two oxygen related vibrational modes associated with each donor. However, we show that the oxygen-only model of the donors is compatible with experiment for a structure involving an insulating core with normal oxygen coordination, surrounded by over-coordinated oxygen atoms which are responsible for the donor activity. It is also shown that the calculated stress-energy tensors for the early donors are in good agreement with the measurements. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Thermal double donors (TDD) are formed by annealing oxygen rich Si or Ge at temperatures between 300°C and 500°C. They comprise a family of at least 16 double donors which form sequentially and are distinguished by their increasingly shallow levels [1]. In spite of extensive studies, they remain a mystery. There are in essence two current models. The first, much favoured in theoretical studies [2–6], suggests that they consist of an increasing number of O atoms surrounding a core containing at least one over-coordinated oxygen defect. The second considers them to be a silicon self-interstitial-oxygen complex I_nO_m [7,8]. It must be admitted that the bulk of experimental evidence favours the latter. Three examples reveal the difficulties of the oxygen-only model. Firstly, the activation energy for the transformation of $\text{TDD}(N)$ into $\text{TDD}(N+1)$ varies

from 1.2 eV for $N = 1$, to 1.7 eV for larger N in Si. This leads to an anomalously fast transformation when compared with the 2.5 eV migration barrier for oxygen [9]. Secondly, EPR and ENDOR studies on the NL8 family, assigned to $\text{TDD}(N)^+$, reveal two shells of O atoms, apparently bridging neighbouring Si atoms, possessing almost infinitesimally small spin-densities [10,11]. The isotropic ^{17}O hyperfine interaction is less than 0.5 MHz in NL8 and much less than 3 MHz found on oxygen in VO^- , in spite of the fact that oxygen in VO^- is located in a nodal plane of the spin-density [12]. How, one wonders, can the source for the donor activity be oxygen when there is so little spin-density associated with it? Thirdly, the oxygen-only model requires an increasing number of oxygen related local vibrational modes (LVMs) to be associated with the later donors, but only at most two such modes have been assigned to any donor [13,14].

Despite the obvious difficulties of the oxygen-only model, it has not been possible, in spite of many attempts, to produce convincing models of self-interstitial-oxygen clusters with the properties of the donors: we found, for example, the well-known IO_2 model from

Ref. [8] to be unstable. Thus, any credible proposal based on an oxygen-only model must also address the three fundamental questions listed above.

We show that this model, perhaps surprisingly, can account for the above difficulties. Further, it also *quantitatively* explains the variation of the piezospectroscopic tensor and the local vibrational modes [15].

The calculations reported here use the first-principles AIMPRO density functional code on cells of up to 160 Si atoms. The details of the method have been given before in an extensive treatment of oxygen defects in Si and Ge [16], and will not be repeated.

2. Formation and diffusion of oxygen chains

We find, in agreement with previous work, that oxygen atoms cluster preferentially along $[110]$ directions with decreasing Si–O–Si angles with increasing chain length (see Fig. 1a). The chains have energies relative to quartz, ranging from 1.81 eV, for the single interstitial, to about 0.36 eV per oxygen atom for the infinite chain. Thus, they are metastable with respect to an SiO_2 precipitate and presumably will break up after sufficiently long anneals.

Consider, now the migration of such chains. As the chain moves through the lattice along the $[110]$ valley in which it lies, a single or group of O atoms moves to the symmetric Y-lid configuration as illustrated in Fig. 1b. An upper limit for the diffusion barrier is found by relaxation with a constraint that forces atoms to approach this configuration [16]. In Si, this energy drops from 2.2 eV for the single oxygen species to 1.4, 1.3 and 1.2 eV for O_n , $n = 2, 3$ and 4. For Ge, there are similar reductions. The observed migration barriers for oxygen in Si is 2.5 eV and hence the theory, in common with other similar calculations underestimates

Fig. 2. Formation energies of VO_n defects and staggered O_n chains, (a) Si, (b) Ge. Formation of each VO_n defect implies the creation of a bulk Si/Ge atom.

the diffusion barriers by about 12–15% [17,18]. Nevertheless a rapid diffusion of oxygen chains is to be expected with a barrier around 1.2 and 1.0 eV in Si and Ge, respectively. The marked reduction of the migration barriers comes from two effects. Firstly, the decreasing Si–O–Si angles which bring the staggered form closer to the Y-lid form, and secondly, the absence of Si dangling bonds at the saddle point for all clusters *except* O_1 . With isolated oxygen concentrations of $\sim 10^{18} \text{ cm}^{-3}$ and maximum donor concentrations of $\sim 10^{16} \text{ cm}^{-3}$ the diffusing chain will most likely encounter a single oxygen interstitial, either lying in the same or a nearby $\langle 110 \rangle$ valley. In the latter case, there will have to be single oxygen jump before a longer chain is formed. It is this rapid chain diffusion which enables long chains to grow rapidly [19], but raises the question as to whether the increasing stress leads to a kick-out of a Si interstitial.

The formation energies of VO_n defects, depicted in Fig. 2, show that the interstitial ejection is exothermic when about four O atoms are clustered. However, at this stage, the barrier to the process will be limited by the formation energy of an I_{Si} or I_{Ge} atom, which we estimate to be around 3.3 eV in both Si and Ge. This implies that at the temperatures where thermal donors are formed, self-interstitials are not produced but rather long chains of oxygen atoms are formed.

Fig. 1. (a) The staggered O_4 chain aligned along $[110]$. (b) Structure close to saddle-point for migration of the chain. This structure could be displaced to 'fall' either into (a) or the structure in (a) displaced along $[110]$. White and black spheres are Si and O atoms, respectively.

3. The O-2NN model

The energies per O-atom of several *periodic infinite* chains were investigated (see Fig. 3). The most stable is the O-2NN model, shown in Fig. 3a, where oxygen atoms are bonded to second neighbour Si atoms in two parallel chains along $[110]$. We found these chains to be bonded ionically together, with each oxygen atom divalent, and each Si atom tetravalent.

It is tempting to identify the O-2NN chains with the donors. Although they have the same C_{2v} symmetry for odd n , this cannot be correct. The band structures for bulk Si and the infinite O-2NN chain, in same supercell, are shown in Fig. 4a and b, respectively. These demonstrate that the chain is insulating with a highest

Fig. 3. Periodic infinite sub-oxide chains. (a) O-2NN. (b) VO₂. (c) O₂-1NN. (d) Ring. (e) D-Ylid. (f) parallel D-Ylid. Formation energies per O-atom are shown on the left-hand side of each structure.

Fig. 4. Band structure for (a) defect-free Si in 48 Si atom supercell, and (b) the same supercell containing the infinite O-2NN chain from Fig. 3a. Solid and dashed lines represent filled and empty states. Band gap of 0.54 eV in (a) is a consequence of density functional theory. Reciprocal-space points are in units of $2\pi/a_0$, where a_0 is the Si lattice constant. Note degenerate valleys along (00 1) and (1 00) in (a) are split in (b). (c) and (d) show band structures for 112 Si atom defect-free supercell and same cell containing O₂-2NN as in Fig. 6. Note that (d) exhibits double donor behaviour.

occupied band close to that of bulk Si. They also reveal that the six degenerate lowest empty bands associated with the $\langle 100 \rangle$ valleys in bulk Si are split in O-2NN, with the lowest pushed downwards by ~ 0.2 eV from their centre of mass by the [00 1] stress arising from

Fig. 5. Contour plot of $|\psi_{nk}(\mathbf{r})|^2 \times 1000$ for (a) the lowest unoccupied band in the infinite O-2NN chain, and (b) the highest occupied band in the O₂-2NN chain. For both, \mathbf{k} -points in the middle of the zone along (0 0 1) were taken. Contour levels are the same in both plots.

oxygen. The ionic character of the sub-oxide is supported by Fig. 5a, which shows that the wavefunction of the stress induced gap level is localized on the Si cations and avoids the oxygen anions as expected for conduction band states in ionic materials.

4. Thermal double donors

Finite O_n-2NN chains are terminated by O-atoms bridging Si nearest neighbours as shown in Fig. 6. Consequently, a topological defect involving an over-coordinated O-atom or an under-coordinated Si-atom, must be present at the interface between the two types of oxygen atoms. The calculations indicate that the former occurs. While short O_n-1NN chains (Fig. 1a), are more stable than short O_n-2NN chains, the reverse is true for long ones and the cross-over occurs around $N = 6$ and 8 oxygen atoms.

Whereas the infinite chain is insulating, the finite chain is not. The highest occupied state in O₂-2NN shown in Fig. 4d now edges the conduction band. It might then be expected that the wavefunction of this shallow double donor level must be localized on the over-coordinated oxygen atoms but, as Fig. 5b shows, this is not the case. The donor state is the *same* stress-induced gap state found for the infinite O-2NN chain. We understand this as follows. The interface region leads to an energy level lying *above* the strain induced gap level due to the O-2NN core. Consequently, electrons drop into the stress induced gap state with minimal overlap with oxygen. This explains the ENDOR/EPR results for a lack of spin-density on oxygen even though oxygen is the source of the donor activity. The strain induced level is also consistent with the effect of uniaxial stress on electronic IR absorption [20].

Fig. 6. O_9 -2NN identified with TDD(4) or TDD(5). This grows along $[1\ 1\ 0]$, and is orthogonal to $[0\ 0\ 1]$. Note over-coordinated oxygen occurs at interface of two types of oxygen.

We can now identify the donors with different oxygen chains. The chains with odd number of oxygen atoms have C_{2v} symmetry but ones with even numbers have C_{2h} symmetry. The vibrational modes of O_2 and O_3 have been identified and these species are not thermal donors [21]. TDD(0) may be identified with a chain of perhaps four or five O atoms suggesting TDD(N) is O_n with $n = N + 4$ or $N + 5$. This agrees with observations that a loss of around 9–10 oxygen atoms per TDD from solution accompanies the formation of the average donor, taken to be TDD(5) or TDD(6) [22,7]. We have also mentioned above that O_n -2NN chains are more stable than O_n -1NN chains for more than 6–8 O-atoms. We are not convinced by the recent suggestion that different donors are alternative conformations with the same number of O-atoms. This is because the barriers between these conformations are too low—around 0.3 eV [19], and stress-alignment experiments show that the donors can be aligned with barriers comparable with single oxygen diffusion. Thus, during stress alignment, the cluster appears to dissociate and subsequently reforms with a different alignment.

Recent high field EPR experiments indicate that the symmetry of all the donors, except the second, is not strictly C_{2v} although the difference appears small [23]. Furthermore, ENDOR studies [10,11] indicate the presence of two shells of ^{17}O hyperfine tensors with axes around 62° with $[0\ 0\ 1]$ and close to that expected from oxygen lying between neighbouring Si atoms. These considerations could be accommodated for example, if the left over-coordinated O-atom in Fig. 6 were shifted one step to the right resulting in a strict loss of symmetry and creating three shells of normal oxygen atoms lying near the ends of the chain.

The compressive stresses exerted by the O-2NN core and O-1NN ends are different. The former lies along $[0\ 0\ 1]$ and the latter along $[1\ 1\ 1]$ and $[\bar{1}\ \bar{1}\ 1]$. Thus the $[0\ 0\ 1]$ displacement of Si along the chains is different for the two regions. Table 1 shows that the central Si atoms exert a very large compressive strain which decreases with the length of the chain. This has implications for the stress-energy or piezospectroscopic tensors for the donors. We have evaluated these tensors in a way described earlier [16]. Table 1 shows that the calculated tensors for the smaller C_{2v} chains possess principal

Table 1

Calculated $[0\ 0\ 1]$ displacements (\AA), $\delta_c(0\ 0\ 1)$ and $\delta_c(0\ 0\ 1)$, of central and end Si-atoms, and stress-energy tensor elements B along $[0\ 0\ 1]$ and $[1\ 1\ 0]$ (eV), for O_n -2NN chains. Observed tensors for the early TDD members were measured by FTIR spectroscopy and EPR (starred values) [24,25]. Note TDD(N) is identified with O_{N+4} -2NN or O_{N+5} -2NN

values very close to those observed by electronic infrared and EPR experiments. Note that O_6 -NN has C_{2h} symmetry, and hence two principal directions of the tensor are rotated by $\theta = 9^\circ$ from the $[0\ 0\ 1]$ and $[1\ 1\ 0]$ crystallographic axes. It is unclear whether this angle lies inside the experimental error for the tensors of those donors displaying lower symmetry than C_{2v} [23]. However, the calculations correctly reproduce the principal values of the stress tensor and their variation with donor species. We note the decreasing $[0\ 0\ 1]$ strain with increasing N would result in shallower strain induced states consistent with the decreasing donor level.

5. Conclusions

In conclusion, we have shown that oxygen atoms lying in chains diffuse quickly and form extended chains lying along $[1\ 1\ 0]$. The most stable long chains involve O-atoms linking second neighbouring Si atoms (O-2NN). The chains are less stable than an SiO_2 precipitate but form through their rapid kinetics. The activation energy for the kick-out of a single Si interstitial appears to be considerable and will not occur during the early-stages at 450°C . The chains give rise to a compressive stress along the $[0\ 0\ 1]$, leading to a stress induced empty gap level lying below the conduction-band, whose effective-mass wave-function is localised on ~ 1000 surrounding Si atoms. The ends of the finite chain are terminated by O-1NN atoms. The donor activity arises from a pair of over-coordinated O-atoms at the interfaces between two species of oxygen in the chain. The energy levels of these regions lie above the stress induced gap level and electrons preferentially occupy the latter.

The two types of oxygen lead to different stress distributions. The core region is highly compressive along [001] while the end region leads to stress along the chain. The magnitudes of the calculated stress-energy tensor are consistent with experimental values. The same model also accounts for the vibrational modes of the donors [15].

It is to be noted that the model suggests that single donors can be formed by substitution of O or Si by group-III or group-V impurities. Other possibilities include substitution of O by a tri-valent complex as a C–H unit. The former probably leads to the NL10(Al) family [26,27] and the later to the H-related shallow thermal donors [28].

Abstract

Process-induced defects are still a key issue in semiconductor device production. The increasing miniaturization and number of process steps as well as the introduction of new materials and processes make the understanding of defect generation more complex. In this paper, we describe small defects in silicon, such as dry etching damage, implantation mask defects, and silicidation defects, which may be considered as nuclei for secondary defect formation. In two examples, transmission electron microscopy and stress simulation are applied to study source-drain transistor leakage and dislocation formation at trench corners in silicon. © 2001 Elsevier Science B.V. Keywords: Dislocation; Stress; Device; Transmission electron microscopy

1. Introduction

Every introduction of a new process or material in semiconductor device manufacturing has entailed defect formation. This has always required elucidating the mechanisms of defect generation in order to optimize device fabrication. The application of continuously improved diagnostic techniques for defect analysis and the correlation to the electrical device performance in a mass production environment was described as a “Gear of Challenge” [1]. Considering today’s economic impact of the microelectronics industry, the “Wheel of Misfortune”—as the control of process-induced defects was described almost 25 years ago [2]—has transformed into a “Disc of Success” [3]. Lately, Bergholz and Gilles [4] reviewed the success story of research on defects in silicon wafer material by emphasizing the continuous input from both academic and industrial research over 40 years! A recent collection of references on the progress of process-induced defects can be found in Ref. [3]. In this paper, we focus first on a selection of

small “harmless” process-induced defects that serve as nuclei for the generation of electrically detrimental defects later in the process. Secondly, we show, by way of example, how stress simulation and analysis may help to eliminate or even avoid defects.

2. Nuclei and primary defects

Failure analysis of single devices in finished integrated circuits by transmission electron microscopy (TEM) reveals, very often, relatively large defects, i.e. having the size of the device feature. To find the root cause, either a detailed TEM analysis of the failure has to be carried out or the possible defect formation mechanism occurring during individual process steps has to be explored by various analytical techniques. Here, we present a few processes where TEM has revealed small lattice imperfections (nuclei) or small dislocations (primary defects) which may incubate electrical malicious secondary defects in a later stage of processing.

Plasma etching, with, e.g. chlorine- and bromine-based chemistry, is used for etching trenches into the silicon substrate which serve as capacitors in memory

chips, or as device isolation, or for vertical transistors. High and uniform etch rates, high selectivity to the etch mask, and others are required for an optimum trench profile. When using a magnetically confined tri-electrode etch reactor, the generation of the reactive species and their extraction towards the substrate may be controlled independently via two separate RF power supplies. Engelhardt [5] showed that the substrate degradation increased with higher bias voltages leading to higher kinetic energies of the species impinging on the surface. Figs. 1a–c are TEM cross sections displaying the silicon (100) surfaces processed with chlorine at low and high RF power level. At low power, only the native oxide layer (Fig. 1a) and an adsorbate of chlorine were detected in Auger spectroscopy profiles, whereas at high power, a larger amorphous zone comprising oxide and amorphous Si (Fig. 1b) as well as chlorine implanted to a depth of about 10 nm were found. The dark spots below the amorphous zone represent point defect clusters and surface roughness, which is more clearly visible in the lattice image of Fig. 1c. These irregularities are potential sites for secondary defect generation: Fig. 2a displays a plate-like NiSi_2 precipitate at a trench sidewall. It was formed after rapid thermal annealing (1200 °C/30 s, N_2) from the inadvertent metal contamination during the etch process. Though it was not directly confirmed, it may be speculated that a strongly degraded surface offers more precipitation sites. Fig. 2b shows a dislocation half-loop nucleated at a 1 μm deep and approximately 0.4 μm wide trench after a 800 °C/450 min wet oxidation. It is interesting that such

Fig. 2. (a) TEM cross section of an NiSi_2 precipitate in silicon at a trench sidewall; (b) TEM plainview of a dislocation generated at an oxidized trench in Si.

dislocations formed only after a particular trench etch condition and chemistry. Geometrical differences in the trench shape or oxide thickness could be ruled out. Thus, the dislocation may have nucleated at the defective amorphous/crystalline trench interface formed after etching and cleaning (such as in Fig. 1c). It was demonstrated in the past that dry etching of contact holes with CHF_3 produces lattice damage [6,7], which gives rise to oxidation-induced stacking faults when no appropriate post-treatment was carried out to remove the damage [8].

Another type of primary defect, generating secondary dislocations, which are, e.g. subject to glide into the substrate due to a stress field, are implantation mask-edge defects. High-dose amorphizing implants give rise to these vacancy-type defects in the silicon substrate below the mask edge. These defects have been observed regularly in various technologies for the last 15 years and are described in detail in Ref. [9]. Fig. 3 is a TEM plainview image showing a long dislocation pinned to a mask-edge defect.

Contact holes, filled with tungsten, use thin barrier layers of Ti/TiN to avoid a reaction with silicon. Due to annealing, finally, a thin TiSi_2 film is created below the TiN. The formation of TiSi_2 from Ti and the substrate causes, first, a compressive stress at elevated temperature whereas this stress becomes strongly tensile when

Fig. 4. TEM cross sections: (a) Defects (arrows) in Si at the bottom of a W-filled contact hole; (b) high-resolution lattice image showing a missing $\{111\}$.

cooling down to RT. When a critical layer thickness is surpassed, the stresses may exceed the critical shear stress on the active slip system (usually $\{111\}\langle 110 \rangle$). [10]. This becomes even worse with decreasing feature size. Moreover, the titanium silicide reaction goes along with volume shrinkage of about 15% and an emission of vacancies into the silicon [11]. Fig. 4a shows a contact hole with about 60 nm in diameter and a relatively thick TiSi_2 layer of about 12 nm. Below both sides of this film, for each contact in the array, defects, 10 nm in size, were generated. A high-resolution image (Fig. 4b) reveals a

half-loop dislocation with a missing $\{111\}$ plane. The dislocations were, thus, produced by the silicidation. They might lower the nucleation barrier for secondary dislocations when a high stress source should become active later in the process.

3. Stress-induced (secondary) defects

The following two examples demonstrate technology processes where secondary defects are released at nuclei due to high mechanical stress fields.

Fig. 5a is a schematic cross section of a power MOS transistor, which showed I_{DSS} leakage, i.e. a

Fig. 5. (a) Schematic cross section of a power MOS transistor; (b) darkfield TEM planview image of a dislocation below the gate oxide; (c) shear stress along a (100) plane 50 nm below the gate oxide after an oxidizing and an inert anneal.

drain-source leakage current at zero gate voltage. TEM planview inspection of such affected transistors identified Lomer-type dislocations lying shallow (ca. 50 nm) below the gate oxide on $\{100\}$ planes (Fig. 5b). They extended from beneath the poly-Si gate edge up to 250 nm into the transistor channel. It was evident that their origins were the mask edge defects at the poly-Si gate edge from the source n^+ -implantation regarding the dislocation lines bowing back to the edge. Their movement on the $\{100\}$ planes must have been released by the injection of silicon interstitials under high lateral stress. Such a phenomenon was described previously by Mader [12] assuming a critical resolved shear stress (RSS) of 1.7×10^7 Pa for glide on $\{100\}$ at 900°C . The critical process step, which led to this failure, was found by 2D-device process stress simulation with TSUPREM-4 [13]. The n^+ -implantation anneal had been carried out in an oxidizing ambient at 900°C for 30 min. Fig. 5c compares the shear stress on a $\{100\}$ plane, 50 nm below the gate oxide and in the direction perpendicular to the gate edge, for an oxidative and an inert anneal. The shear stress could be reduced by 50% for nitrogen anneals. This sufficed to avoid the defect formation and leakage. We note that the calculated stress at the dislocation nucleation point exceeded the critical RSS reported in Ref. [12] in both cases by factors of 10 and 20. Transistors with similar leakage behavior were also observed by other authors [14,15].

Trenches in the silicon substrate are usually filled with poly-Si or oxides, which have high intrinsic stress

leading to strong compressive or tensile stress at the trench corners [16]. During the development of a novel read-only memory with trench technology [17], dislocations gliding on $\{111\}$ planes were generated in an early version of the device at the bottom corners (TEM cross section in Fig. 6a, planview image in Fig. 6b). The device consisted of long trenches with several vertical transistors on both trench sidewalls. The stored information differed whether the gate was accomplished with poly-Si, or filled with tetraethylorthosilicate (TEOS) oxide. TEOS also isolated the transistors in the long trenches. First, the trenches were completely filled with TEOS. During a successive anneal, the TEOS became densified and shrunk by approximately 7%. The TEOS was then etched and substituted by poly-Si according to the programming. The final process, which did not use TEOS, did not generate dislocations. For both cases, 2D stress simulations with TSUPREM-4 were carried out. The shear stresses on $\{111\}$ planes are tensile at the bottom corners. The linescans of the shear stresses on $\{111\}$ planes ("A" and "B" in Fig. 6a) are plotted in Fig. 6c. For the plane "A", the stress is compressive in the corner (-4×10^7 Pa) whereas for plane "B", it is tensile (7×10^7 Pa). The stresses at the bottom corners are about 50% higher for the process with TEOS. For the $\{111\}$ plane "A", a 60° dislocation would come to rest at about 400 nm from the trench corner when considering a critical RSS of $0.1\text{--}0.6 \times 10^7$ Pa for glide on $\{111\}$ [16]. In case of the $\{111\}$ plane "B", the resting distance would be 150 nm. This fits for the closest

Fig. 6. (a) TEM cross section of a trench in Si filled with poly Si and TEOS. Dislocations (arrows) lie on common $\{111\}$ planes A and B; (b) TEM planview image of a trench with the generated dislocations parallel to the bottom corner; (c) shear stress along $\{111\}$ for process with (A, B) and without (A', B') TEOS.

dislocations observed in Figs. 6a and b only. In this situation, the nucleation stress exceeded the critical RSS by a factor of 10.

In future, a quantification of the local mechanical stresses becomes desirable. This requires one to predict the stresses necessary for dislocation nucleation correctly and to estimate the influence of the nuclei. Presently, efforts are being undertaken to measure the local strains with high spatial resolution by convergent beam electron diffraction in the TEM and comparing these values with stress simulations [18,19].

4. Conclusion

The mechanisms for defect generation have, in principle, stayed the same over the years, but it becomes a more complex and delicate matter to trace the root cause in today's technology. More than ever, it is important to recognize and eliminate the defects in the development or early phase of production to ensure economic yield and device reliability. Therefore, a kind of premonition system for defect generation could be envisaged. It should comprise a better understanding of the various nuclei for defect generation, and of the stresses occurring during processes, as well as local stress measurement techniques with high spatial resolution.

Optical study of GaN:Mn co-doped with Mg grown by metal organic vapor phase epitaxy

R.Y. Korotkov, J.M. Gregie, B. Han, B.W. Wessels*

Department of Materials Science and Engineering, Northwestern University, Materials and Life Science Building, 2225 N. Campus Drive, Evanston, IL 60208-3108, USA

Abstract

Optical properties of a series of semi-insulating Mn-doped GaN co-doped with Mg were studied using photoluminescence (PL). A strong PL emission band at 1.0 eV was observed upon co-doping. The new band exhibited a rich fine structure with peaks at 1.057, 1.048, 1.035, 1.032, 1.020, 1.014, 1.008, 1.000 and 0.988 ± 0.001 eV. The integrated and relative intensities of these lines varied as a function of the Mn concentration and excitation source. The measured luminescence decay time was 20–95 μ s and depended on emission energy. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Photoluminescence; Mn doping

1. Introduction

The luminescence properties of the transition metal element Mn have been widely studied in III–V semiconductor compounds [1–3]. Manganese preferentially incorporates on the metal site forming an acceptor. Photoluminescence (PL) studies have shown that Mn can form donor–acceptor pairs (DAP) in these compounds. Furthermore, manganese has been shown to have intra-atomic transitions involving the d-shell electrons. The identification of the specific transition involved in optical spectra is often complicated by the presence of the two types of transitions [3,4]. Substitutional Mn will form the Mn^{2+} (d^5) and Mn^{3+} (d^4) states if placed on the cation site in III–V compounds [1–4]. It has been shown that three defect centers are formed in III–V semiconductors. They are a neutral acceptor, A^0 (d^4), an ionized acceptor (when an electron is captured by the A^0 from the valence band (VB)), A^- (d^5) and a neutral acceptor formed by a complex with a hole, A^0 ($d^5 + h$) [5]. A negative acceptor (A^-) and complex ($d^5 + h$) were observed for the GaAs:Mn, whereas the A^0 and A^- states were detected in GaP [5]. In GaN, the d^5 ion configuration was observed in EPR studies of

unintentionally doped [6] and intentionally Mn-doped GaN [7,8].

Little is known about the Mn-related optical emission and absorption GaN. It is expected that the spin forbidden transition within Mn d^5 ion will have low intensity and long lifetime. We have recently investigated the absorption and PL spectra of Mn-doped epitaxial GaN [9]. A weak broad band was observed at 1.25 ± 0.02 eV in the PL spectra of Mn-doped samples with the full-width at half-maximum (FWHM) of 250–300 meV for above band gap excitation. The independence of the energy peak position of this band with temperature and a long ~ 8 ms decay times indicated that it was likely related to the spin forbidden transition, $^4\text{T}_1\text{--}^6\text{A}_1$ of Mn (d^5) ion [10]. The energy position for this band was similar to that (1.3 eV) for $^4\text{T}_1\text{--}^6\text{A}_1$ recombination observed for Fe^{3+} in GaN [11].

In this paper, PL properties of the GaN:Mn co-doped with Mg are investigated. A new strong PL band with a rich structure is observed on the low energy side of the 1.25 eV band previously reported in Mn-doped GaN samples [9].

2. Experimental

The MOVPE growth of the Mn-doped GaN layers has been previously described [9]. For the Mn, Mg co-

*Corresponding author. Tel.: +1-847491-3537; fax: +1-847-491-7820.

E-mail address: b-wessels@nwu.edu (B.W. Wessels).

doping experiments, the Mg source partial pressure was $0.18 \mu\text{mol}/\text{min}^1$ and Mn source partial pressure was varied in the broad range from 0.02 to $5 \mu\text{mol}/\text{min}$. The epitaxial layer consisted of a 20 nm GaN nucleation layer, a 500 nm Mg-doped ($0.03 \mu\text{mol}/\text{min}$) layer grown at 1060°C , and a 2–2.5 μm thick Mn, Mg co-doped layer grown at 1060°C . As-grown Mn–Mg epilayers had semi-insulating behavior. The Mg co-doped samples were annealed at 850°C to produce p-type material. Photoluminescence spectra were measured over the spectral range of 0.7–1.2 eV. Photoluminescence was excited with either the 325 nm line of a He–Cd laser or a semiconductor laser with excitation wavelength of 973.8 nm. The excitation densities of these lasers were 0.32 and $3 \text{ W}/\text{cm}^2$, respectively. The PL signal was dispersed by a Zeiss monochromator with a resolution of 2 meV at $1 \mu\text{m}$ and detected with a high sensitivity Ge-detector and a lock-in amplifier. The sample temperature was varied from 20 to 300 K using a closed cycle helium cryostat. The He–Cd laser intensity was varied using neutral density filters in the range of 2×10^{-3} – $10 \text{ W}/\text{cm}^2$. All PL spectra were normalized to account for the spectral responsivity of the Ge-detector as well as the monochromator. Transient PL decay curves were excited using 500 MHz pulsed 974 nm laser. The system resolution was limited by the Ge-detector rise time of 16 μs .

3. Results and discussion

A new strong band with a peak at approximately 1.0 eV was observed in the PL upon co-doping with Mg. It was composed of a series of sharp lines with FWHM of ~ 3 – 10 meV . A PL spectrum of this fine structure obtained with below band gap excitation (974 nm) is shown in Fig. 1. Note, however, that the 1.25 eV PL band observed in Mn-doped samples was not detectable above the excitation 974 nm laser noise suggesting that the new sharp emission was activated in GaN:Mn by co-doping with Mg.² The major energies of the sharp lines observed in the co-doped samples spectra are summarized in Table 1. They are at 1.057, 1.048, 1.035, 1.032, 1.020, 1.014, 1.008, 1.000 and $0.988 \pm 0.001 \text{ eV}$. A few weak transitions were also observed on the lower energy side of the main band as seen in Fig. 1. This fine structure was observed with both extrinsic and intrinsic

Fig. 1. PL spectrum for one of the co-doped samples (RK 340) obtained with 974 nm excitation at 20 K. The energies of the fine structure are listed in Table 1 for the strongest lines.

excitation sources [12]. It was observed with above band gap energies of 325 nm He–Cd laser as well as below band gap 632.8 and 974 nm lasers. The positions of the peaks were the same for these excitation sources. However, the integrated and relative intensities varied as a function of the excitation wavelength indicating that each major separate emission line is likely to have its own excitation spectra.

To study the effect of Mn concentration on the integrated intensity of the 1.0 eV band, a series of co-doped films were grown with different Mn concentrations. In this experiment, the Mg acceptor concentration was constant, whereas the Mn concentration varied. The normalized PL spectra for this series of samples are shown in Fig. 2. The integrated intensity of the 1.0 eV band increased at first with the increase of Mn-partial pressure and then decreased [12]. Note that the energy positions of the sharp emission lines were the same for these samples indicating that the optically active centers involved were of the same nature in all studied samples. However, relative intensities of these lines varied as a function of the Mn concentration indicating that the concentration of the optically active centers involved in the separate sharp lines changed with Mn concentration.

To detail the nature of the 1.0 eV band it was studied as a function of temperature and excitation intensity. Thermal quenching of the luminescence was studied under 974 nm excitation. All bands except one were thermally quenched above 100 K with activation energy of $\sim 70 \text{ meV}$ as shown in Fig. 3.³ The intensity of the

¹This Mg partial pressure was used to achieve $p = 2 \times 10^{17} \text{ cm}^{-3}$ in Mn-doped GaN [13].

²It is important to note that our undoped GaN samples did not exhibit emission bands in the near infra-red. Previously observed Co^{2+} , $(\text{Cr}^{4+}/\text{Ti}^{2+})$ and Fe^{3+} emission bands at 1.047, 1.19 and 1.3 eV [1,14] were not detected in our undoped GaN samples. Therefore, the observed fine structure is specifically related to the Mn–Mg co-doped samples.

³A slightly different activation energy of 0.1 eV was calculated for the experimental data obtained under 325 nm excitation.

Table 1

Energy positions and lifetimes of sharp peaks observed in Mg co-doped GaN:Mn samples and Mn-doped samples (1.25 eV band)

Energy (eV)	1.057	1.048	1.034	1.032	1.02	1.013	0.988	0.986	0.95	1.25
τ (μ s)	40	95	68	68	52	42	54	54	49	8000

Fig. 2. Above band gap excited (325 nm) PL spectra of co-doped samples at 20 K grown with different Mn concentrations. The Mg partial pressure was constant (0.18 μ mol/min). The Mn partial pressures were 4.54, 1.36, 0.079 and 0.02 μ mol/min for samples RK 341, RK 340, RK 338 and RK 337, respectively.

highest energy transition observed at 1.057 eV first increased from 20 to 100 K and then decreased with the increase of the temperature, $T > 100$ K. The increase of 1.057 eV band was likely due to interactions with phonons. The PL intensity of the lines comprising the 1.0 eV band increased linearly with excitation power as shown in Fig. 4 for selected transitions under 325 nm excitation. In addition, for below band gap excitation the intensity of the sharp structure linearly increased with excitation power [12].

To determine whether these emission lines were associated with intra-d shell transitions, the luminescent recombination lifetime was measured on the co-doped samples. A PL decay curve for transitions at 1.032 eV is shown in Fig. 5. The PL intensity decayed exponentially at low temperature (20 K). The decay time was 66 μ s. The lifetime of the sharp lines (40–90 μ s) in the co-doped samples was two orders of magnitude smaller than that observed for the characteristic 1.25 eV Mn band for the Mn-doped GaN samples [10]. In this case, the lifetime was of the order of ~ 8 ms. Furthermore, each emission line had slightly different recombination lifetime, as shown in Table 1, suggesting that emission lines in the

Fig. 3. Thermal quenching of the individual transitions of the 1.0 eV band excited with 974 nm excitation.

Fig. 4. Excitation intensity dependence of the PL intensity for three sharp lines obtained with above band gap excitation (325 nm) at 20 K.

fine structure are associated with different recombination centers.

The dramatic change in the luminescence spectra of Mn doped GaN upon co-doping with Mg was unexpected. Its origin is not understood. Co-doping with Mg acceptors may potentially lead to several changes in

Fig. 5. Transient PL spectra of one of the co-doped samples obtained at 1.032 eV, 20 K. The calculated exponential decay (66 μ s) is shown with a solid line. System response of 16 μ s is shown for comparison.

the optical behavior of Mn. Addition of Mg could lead to complex formation. Furthermore, interactions with Mg may distort the Mn-ion surroundings. The alteration of the Mn-ion (d^5) surroundings changes the environmental symmetry of Mn ion leading to the breakdown of the selection rules by the appreciable sextet–quartet mixing [2,3]; consequently, the forbidden $^4T_1-^6A_1$ transition becomes allowed. The decrease of the lifetime for the 1.0 eV PL band by two orders of magnitude from 8 ms observed in Mn-doped GaN seems to support changes in local symmetry in co-doped samples.⁴

While co-doping with Mg could lead to changes in local symmetry, addition of Mg acceptors will also lower the Fermi energy, potentially leading to a change in the charge state of Mn. In addition, lowering of the Fermi level will result in increased compensation of the p-doped GaN with donors, D. An alternative explanation is that the observed fine structure could involve $Mn^{3+}-D$ and $Mn^{2+}-D$ centers. The alteration of the Fermi energy upon co-doping could potentially stabilize one of these complexes. Indeed a model involving transitions from $Cr^{3+}-D$ to $Cr^{2+}-D$ was proposed to explain the fine structure consisting of 19 lines observed in absorption spectrum of Cr in GaAs [4].

⁴The fact that the observed fine structure in co-doped GaN is formed on the low energy side of the 1.25 eV band in GaN:Mn can be explained by the fact that in the moderately doped GaN:Mn, two exponential decays were observed with the lifetime of 200 μ s centered at 1.38 ± 0.02 eV and 8 ms centered at 1.1 ± 0.05 eV [9,14]. The last transition was assigned to $^4T_1-^4A_1$ recombination of Mn in GaN.

4. Conclusions

In conclusion, the luminescent properties of semi-insulating Mn-doped GaN co-doped with Mg were studied. Upon co-doping, a strong PL band at 1.0 eV was observed. The PL band displayed a rich fine structure at low temperature. It is comprised of at least 10 emission lines separated by 2–10 meV. The FWHM of these lines varied from 3 to 10 meV and was limited by the resolution of the monochromator. Transient spectroscopy measurements indicated the 1.0 eV PL band decayed exponentially with a lifetime of 20–90 μ s. The measured lifetimes were at least two orders of magnitude shorter than that observed for the $^4T_1-^6A_1$ transition at 1.25 eV in Mn-doped GaN.

Abstract

Rare earth (RE) ions implanted GaN films were studied by optical spectroscopy and RBS techniques. Sharp emission lines due to intra-4fⁿ shell transitions can be observed even at room temperature for the Eu³⁺ and Pr³⁺. The photoluminescence spectra recorded by the above band gap excitation reveal dominant transitions due to the ⁵D₀→⁷F_{1,2,3} lines at 6004, 6211 and 6632 Å for the Eu³⁺ and ³P_{0,1}→³F_{2,3} at 6450 and 6518 Å, respectively, for the Pr³⁺. We report on the temperature dependence of the intra-ionic emissions as well as on the lattice site location of the RE detailed angular scans through the <0001> and <10 $\bar{1}$ 1> axial directions; which indicates that for Pr, complete substitutionality on the Ga sites was achieved while for Eu a Ga displaced site was found. © 2001 Elsevier Science B.V. Keywords: GaN; Implantation; PL; RBS

1. Introduction

Eu³⁺ and Pr³⁺ are known to be efficient activators in several hosts giving rise to strong red luminescence from the ⁵D_J→⁷F_J and ³P_J→³F_J multiplets, respectively [1–11].

It is known that these rare earth (RE) ions can be incorporated into the GaN samples either by the in-grown process [12–16] or the ion implantation technique [17–22]. Its narrow emission lines associated with the weak dependence of intensity on temperature put into evidence the possibility of achieving full color display devices based on the GaN using the intra-4fⁿ transitions from the RE ions, where Eu³⁺ or Pr³⁺ stands for the red emission, Er³⁺ for the green and Tm³⁺ or Ce³⁺ for the blue [13–16,23]. Actually, yellow and orange emissions were achieved from the ELDs fabricated on the GaN films codoped with Er and Eu [16]. Despite the

progress made in the GaN devices doped with the RE ions, the fundamental properties of intra-ionic luminescence are far to be exploited.

In this work, we focus on the photoluminescence (PL) and RBS studies of the Eu and Pr implanted GaN samples. From the experimental data, the site symmetry of the RE ions in the GaN is discussed and a tentative assignment of the emission levels is made.

2. Experimental

The wurtzite undoped ($n < 5 \times 10^{16} \text{ cm}^{-3}$) GaN layers were epitaxially grown by Metal Organic Chemical Vapor Deposition on c-plane sapphire substrates with a thickness of 1.3 μm. The Eu³⁺ and Pr³⁺ were implanted at room temperature with an energy of 160 keV and at doses of $D = 5 \times 10^{14} \text{ cm}^{-2}$. The measured implantation ranges were determined to be 40 nm. The samples were annealed in a rapid thermal annealing apparatus between graphite strips under flowing N₂ gas at 1000°C for 120 s. The RBS/channelling studies were

performed with a 1 mm diameter collimated beam of 2 MeV He^+ ions. The backscattered particles were detected at 140° and close to 180° with respect to the incoming beam direction using silicon surface barrier detectors with the resolutions 13 and 16 keV, respectively. Full angular scans were carried out across the $\langle 0001 \rangle$ and the $\langle 10\bar{1}1 \rangle$ axial directions using a two-axis goniometer.

The PL measurements were carried out with a 325 nm CW He–Cd laser and the excitation power density was typically less than 0.6 W cm^{-2} . A 325 nm band pass filter was used to attenuate lines other than the 325 nm laser line and a low pass sharp cutoff filter was used to stop the laser light. The PL was measured at temperatures between 14 and 300 K using a closed cycle helium cryostat. The luminescence was dispersed by a Spex 1704 monochromator (1 m , 1200 mm^{-1}) and detected by a cooled Hamamatsu R928 photomultiplier.

The Raman spectra were obtained at room temperature in a Jobin Yvon—Spex T64 000 using the 514.5 nm line of an Ar ion laser as excitation source.

3. Results and discussion

In Fig. 1, a comparison between the visible intra- $4f^6$ luminescence observed in the Eu^{3+} implanted GaN and in-grown doped samples is shown. The PL spectra were obtained by the above band gap excitation at 14 K. The $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition produces the strongest emission lines, either at 14 K or at room temperature, for both samples. Minor lines are observed in the studied spectral range. The lines were tentatively assigned to different $^5\text{D}_{0,1} \rightarrow ^7\text{F}_{0,1,2,3,4}$ transitions in accordance with the previous results for the Eu^{3+} in several hosts [3–12, 14–16]. One of the main features concerning the two emission spectra is the appearance of the forbidden $^5\text{D}_0 \rightarrow ^7\text{F}_0$ transition in the in-grown sample, due to admixture with other J levels, being undetected in the implanted sample.

It has been pointed out that the trivalent RE ions in the GaN assume a substitutional Ga site being in a relaxed C_{3v} symmetry [9,17]. In accordance with this site symmetry, the state with $J = 2$ splits into a nondegenerate A level and a two-fold degenerated E level. Even in this site symmetry, three lines for the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition have been reported [11] due to further splitting of the E level. The PL spectra put in evidence that in both samples, the ion must be in a lower site symmetry than the referred trigonal symmetry [9,17] as observed by a closer view of the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ emission in the implanted sample (inset (b) of Fig. 1) and in the in-grown sample, where a total lift of the J -degeneracy of the multiplets can be seen. The likely candidates for the lower site symmetry of the RE ions are C_2 , C_i , C_1 , C_{2v} , D_2 , D_{2h} , C_{2h} and C_{1h} site

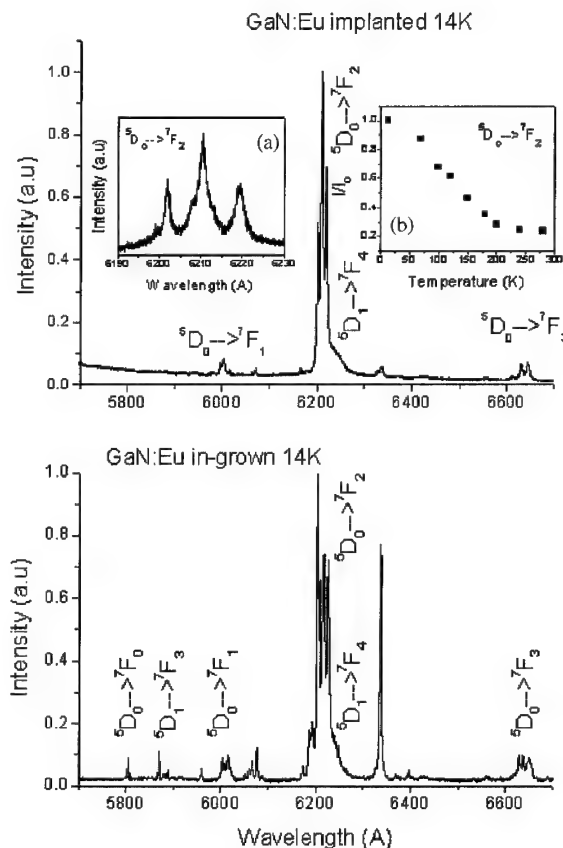

Fig. 1. The PL spectra of the implanted and in-grown GaN samples obtained by the He–Cd excitation at 14 K. In the inset (a) of the upper picture, a high resolution of the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition for the implanted sample is present. The inset (b) shows the dependence of the integrated intensity on the temperature for this transition, obtained under constant illumination.

symmetries. However, from the fact that the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition is the strongest one, we can exclude the hypothesis that the ion is located in sites with inversion symmetry in both samples. This fact associated with the missing of the $^5\text{D}_0 \rightarrow ^7\text{F}_0$ transition in the implanted sample allows one to tentatively assign the ion site symmetry to the D_2 point group. Some of the observed lines in the PL spectra cannot be directly assigned to the intra- $4f^6$ transitions. They are probably either due to the anti-Stokes luminescence or cooperative vibronic transitions as being currently observed for the triply ionized RE ions in several hosts, even at low temperatures [24–31].

The Raman spectra performed in a $z(xz)\bar{z}$ configuration at room temperature for both implanted samples (Eu and Pr) presents, besides the characteristics E_2 and $\text{A}_1(\text{LO})$ of the GaN lattice, two local modes at 362 and 380 cm^{-1} as previously observed in the implanted samples [32]. In order to test if they are related to

Fig. 2. The PL spectra of the Pr implanted GaN sample obtained by the He–Cd excitation at 14 K. In the inset (a), the dependence of the integrated intensity on temperature, obtained under constant illumination, for the $^3P_0 \rightarrow ^3F_2$ transition is shown. The inset (b) shows the Raman spectra of the Eu and Pr implanted samples.

vibronic transitions. excitation luminescence (PLE) studies will be done.

In the inset (b) of Fig. 1, the dependence of the PL integrated intensity with the temperature for the $^5D_0 \rightarrow ^7F_2$ transition is shown. The intensity decreases near one order of magnitude in the studied temperature range.

Similar spectroscopic studies were performed for the Pr implanted GaN samples. The PL spectra obtained by the above band gap excitation at 14 K are shown in Fig. 2. The dependence of the PL integrated intensity

with the temperature of the $^3P_0 \rightarrow ^3F_2$ transition, as well as the previously mentioned Raman spectra of both implanted samples, are added.

The strongest emission lines are identical to those previously observed by several authors for the $^3P_0 \rightarrow ^3F_2$ transition [18,19,21] indicating that the Pr^{3+} ion is in C_{3v} symmetry. The lines are slightly displaced in energy and they are sharper than those previously reported [21]. Similar to the Eu^{3+} luminescence, the dependence of the integrated intensity on the temperature for the $^3P_0 \rightarrow ^3F_2$ transition decreases near one order of magnitude in the studied temperature range (inset (a) of Fig. 2).

The lattice site location of the Pr and Eu was done performing detailed angular scans through the $\langle 0001 \rangle$ and $\langle 10\bar{1}1 \rangle$ axes. For the $\langle 0001 \rangle$ axis, both the Pr and Eu curves coincide with the Ga one (not shown) indicating that the RE are located along this direction [33]. However, for the $\langle 10\bar{1}1 \rangle$ axis, while the Pr and Ga curves nearly overlap, the Eu curve is narrower, as shown in Fig. 3. This fact indicates that the Eu ions are displaced towards the middle of the $\langle 10\bar{1}1 \rangle$ axis. According to the simulations [33], the curve can be well reproduced by a displacement of 0.2Å along the $\langle 0001 \rangle$ axis. The RBS/C data put in evidence that the Eu^{3+} is in a Ga displaced site. This is in accordance with a lower site symmetry for the RE ion.

4. Conclusions

The PL and RBS analyses were made in the Eu and Pr implanted GaN samples. The results indicate that the Eu^{3+} is in lower site symmetry than trigonal C_{3v} symmetry both in the implanted and in-grown samples. In the last one, more than one environment for

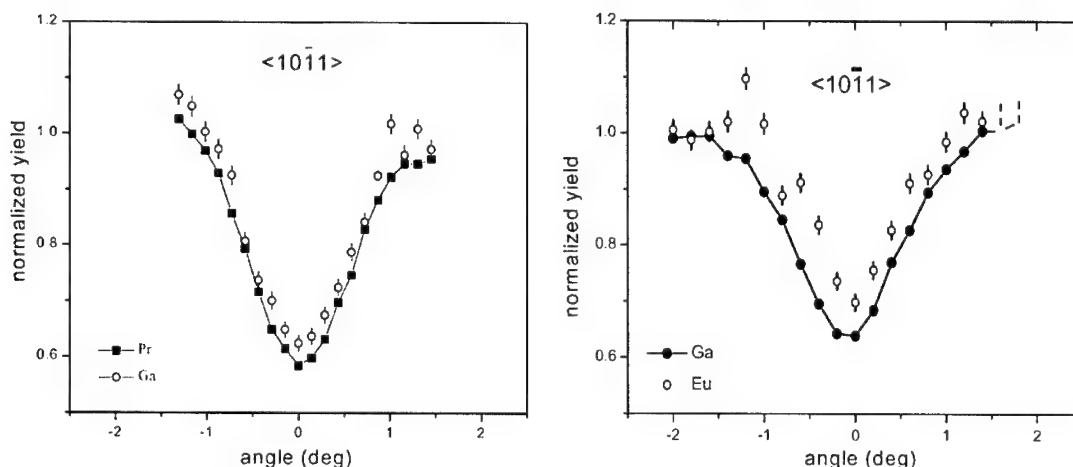

Fig. 3. The angular scans along the $\langle 10\bar{1}1 \rangle$ direction for the GaN films implanted with the Pr (left) and Eu (right) after annealing at 1000°C for 120 s. Both samples were implanted with a nominal dose of $5 \times 10^{14} \text{ cm}^{-2}$.

the Eu^{3+} may coexist. For the Pr implanted samples, the data pointed to a substitutionality of the ion in the Ga sites. For both implanted ions, a decrease close to one order of magnitude for the integrated intensity dependence on temperature is observed. Some of the observed PL lines are probably due to cooperative vibronic transition. In order to get further information on the nature of these emission lines, the PLE measurements are under way.

Investigation of the defect structure of GaN heavily doped with oxygen

R.Y. Korotkov, F. Niu, J.M. Gregie, B.W. Wessels*

Department of Materials Science and Engineering and Materials Research Center, Northwestern University, 2225 N. Campus Drive, Evanston, IL 60208-3108, USA

Abstract

The defect structure of oxygen-doped GaN grown by MOVPE was investigated. At high oxygen pressures, a super-linear increase of electron concentration as a function of partial pressure was observed. Electron concentrations as high as $7 \times 10^{19} \text{ cm}^{-3}$ were measured. Formation of micropits was observed by scanning electron microscopy in heavily doped samples. Cross-sectional transmission electron microscopy studies indicated the presence of epitaxial precipitates located on the cavity surface. The precipitates are believed to be related to gallium oxide. Using spatially resolved photoluminescence (PL), a broad PL band at 3.56 eV was observed near the micropit regions. The band was attributed to free-electron recombination from the highly degenerate areas associated with oxygen. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: O-doped GaN; Microcavities; Photoluminescence

1. Introduction

Oxygen is known as a potential source of residual donors in GaN, although its doping behavior is not well understood [1–4]. The electrical properties of oxygen donors in GaN are somewhat controversial. Ionization energy values have ranged from 4 to 75 meV as determined by Hall-effect and optical measurements [1,5–8]. This large variation can be partially attributed to difficulties in their determination from Hall effect, presumably due to sample dopant inhomogeneities. A low temperature-conductivity tail is observed even in moderately doped GaN:O [8,9], which complicates calculations. Two possible explanations that account for this effect are the presence of a high conductivity layer at the layer substrate interface [10] or the formation of an impurity band [7]. SIMS studies corroborate the former model, since large concentrations of oxygen were observed within the first micron of the GaN film [11].

While it is now generally believed that oxygen is the shallow donor often responsible for the high residual background n-type conductivity in GaN, there are still unanswered questions regarding its incorporation. For example, we previously demonstrated that the electron concentration, n , increased with increasing partial pressure of oxygen as the square root from 1×10^{17} to $8 \times 10^{18} \text{ cm}^{-3}$ [8]. However, it was also observed that the electron concentration increased super-linearly at higher oxygen partial pressures. In this paper, we present structural, optical, and electrical characterization of heavily oxygen-doped epilayers. Hexagonal surface microcavities (micropits) are formed on the surface of heavily oxygen-doped samples with $n > 10^{19} \text{ cm}^{-3}$. Spatially resolved photoluminescence (PL) data provide evidence that the observed emission band at 3.56 eV is associated with oxygen doping and the presence of micropits.

2. Experimental

Oxygen-doped GaN epilayers were grown by MOVPE, as described elsewhere [8]. In brief, after deposition of the GaN buffer layer at 600°C, the

*Corresponding author. Tel.: +1-847-491-3537; fax: 1-847-491-7820.

E-mail address: b-wessels@northwestern.edu (B.W. Wessels).

temperature was ramped to 1060°C and 50 nm of undoped GaN was deposited. This step was followed by the deposition of 2 μm of oxygen-doped GaN. Scanning electron microscopy (SEM) images were taken using a Hitachi S-4500 microscope. Typical operating conditions were 5–20 kV, with a magnification of 50–30,000 \times . High-resolution TEM was carried out with a Hitachi HF-2000 cold field emission microscope operating at 200 kV. The PL measurement setup was previously described [12]. He–Cd laser excitation was used. For spatially resolved measurements, the laser was focussed to a spot size of 20 μm .

3. Results and discussion

The surface morphology of deliberately oxygen-doped GaN was investigated. The surface of as-grown, undoped GaN films as seen in Fig. 1(a) is featureless when grown at high temperatures (1000–1070°C). As the partial pressure of oxygen is increased, the surface morphology remains unchanged for carrier concentration $<10^{19}\text{cm}^{-3}$. At this concentration, hexagonal-shaped microcavities are formed on the surface, as seen in Figs. 1(b) and (c). The concentration of the pits increased with free electron concentration, as seen by comparing Figs. 1(b) and (c), indicating that the formation of these surface microcavities was oxygen-related. The surface of the oxygen-doped sample with a RT electron concentration of $7 \times 10^{19}\text{cm}^{-3}$ was rough and completely covered with pits. A high-magnification SEM image of one of the microcavities is shown in Fig. 1(d).

Table 1

Electrical properties of GaN:O films

Sample	$P(\text{O}_2)$ (Pa)	T (K)	NH_3 (sccm)	$n \times 10^{18}$ (cm^{-3})

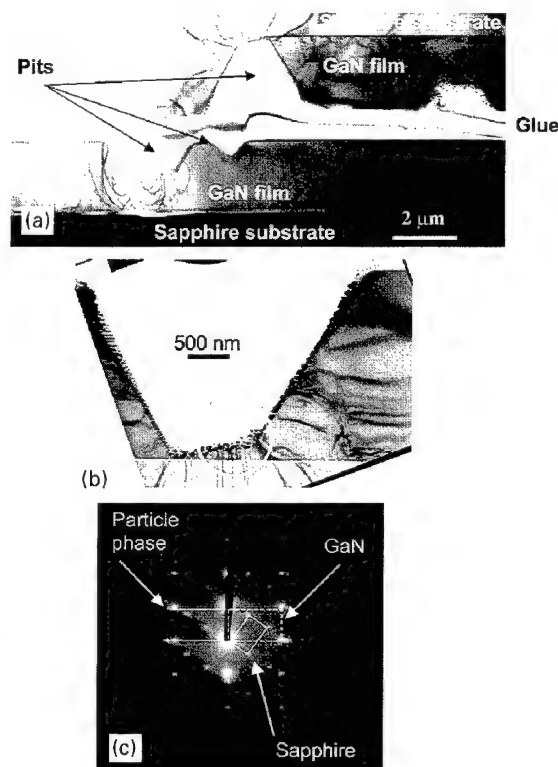

Fig. 2. (a) XTEM micrograph of GaN films grown on sapphire showing O-doping induced pits, (sample RK234, $n = 2 \times 10^{19}\text{cm}^{-3}$); (b) high-resolution XTEM image of a deep pit, with visible precipitate formation on the sidewalls; (c) SAD pattern of circled region of (b) that includes the $\text{Al}_2\text{O}_3/\text{GaN}/$ particle interface.

To determine the structure of the microcavities, TEM studies of highly oxygen-doped layers were conducted. A cross-sectional micrograph of a highly oxygen-doped sample RK234 (see Table 1) is shown in Fig. 2(a). It shows two pieces of a GaN sample grown on sapphire attached to each other by glue introduced during TEM sample preparation. Several pits are evident at the

Fig. 1. SEM planar view image of oxygen-doped samples with (a) $n = 8 \times 10^{18}$, (b) 2.1×10^{19} , (c) $1.1 \times 10^{19}\text{cm}^{-3}$ and (d) high-resolution image of the pit.

surface of the GaN films. The depth of the pits varied, with some pits originating at the buffer layer surface. At the same time, several pits that nucleated during later stages of the GaN growth were also observed. Interestingly, a new epitaxial compound in the form of grains was observed on the pit surface (Fig. 2(b)). The structure of these grains was analyzed and compared to bulk GaN using selective area diffraction (SAD) patterns as shown in Fig. 2(c). Based on the fact that the SAD pattern of the grain regions was aligned in the same crystallographic direction as the GaN, it was concluded that these grains formed a textured epitaxial arrangement with GaN. The detailed work will be published elsewhere [13,14]. However, as to the identification of this second phase, we propose that it is likely a gallium oxide phase such as Ga_2O_3 or $\text{GaN}_x\text{O}_{1-x}$. The formation of a second phase of oxide at high partial pressures of oxygen is predicted from thermodynamic calculations [3]. The present study indicates that the solubility limit of oxygen in epitaxial GaN is of the order of $1 \times 10^{19} \text{ cm}^{-3}$.

PL measurements at 20 K were conducted on heavily oxygen-doped GaN layers to determine whether or not oxygen introduces radiative centers. The samples studied are summarized in Table 1. A PL spectrum of a moderately O-doped sample (RK216) is shown in Fig. 3 for comparison. It consists of a strong donor-bound exciton (DBE) (FWHM = 5 meV) PL band located at 3.482 eV with a smaller shoulder of the free exciton (FE) at 3.49 eV, and so-called two-electron transitions at 3.458 and 3.463 eV, respectively. The exciton transitions are assigned by comparing their temperature-quenching behavior, and are in line with earlier results [5]. In heavily oxygen-doped samples, two DBEs were observed as shown in Fig. 3. The most intense exciton transition was at 3.482 eV for O-doped

samples with $n < 1 \times 10^{19} \text{ cm}^{-3}$, and at 3.472 eV for the samples with higher electron concentrations. Since the intensity ratio of the DBE transition at 3.482 eV to the FE transition was independent of partial pressure of oxygen, it was concluded that it did not involve an oxygen-bound exciton. In contrast, the relative PL intensity of the 3.472 eV DBE to the FE peak increased with partial pressure of oxygen as seen in Fig. 3. Therefore, we attribute the PL peak at 3.472 eV to an oxygen-related bound exciton.

The PL spectrum of a highly oxygen-doped ($2 \times 10^{19} \text{ cm}^{-3}$) sample also exhibited a broad band extending to energies above the band gap in addition to the FE, DBE and ABE transitions. The band was observed above band gap as a shoulder to the FE and DBE transitions at 3.56 eV, as seen in Figs. 3 and 4. The intensity of this band increased with increasing partial pressure of oxygen, indicating that it was sensitive to the incorporation of oxygen in the film. As seen from this figure, the 3.56 eV band broadened when the electron concentration was increased (Table 1). However, no separate peak was observed, even at the highest electron concentration (RK232). The 3.56 eV band was only observed in heavily O-doped samples with electron concentrations higher than 10^{19} cm^{-3} . We propose that the 3.56 eV band observed in highly oxygen-doped samples is due to free electron recombination.

To identify the origin of this band in highly oxygen-doped samples, spatially resolved PL experiments were conducted.¹ It can be seen in Fig. 4 that the intensity of the 3.56 eV band is higher in the pit regions than in nearly pit-free areas. Therefore, the 3.56 eV band PL is associated with the regions covered by hexagonal pits. The degenerate regions are formed in the vicinity of the hexagonal pits in agreement with spatially resolved PL, SEM, TEM and SIMS data. A similar broad, asymmetric band was previously observed in HVPE-grown, undoped GaN. In that case, it was related to localized degenerate regions using spatially resolved cathodoluminescence [15].

4. Conclusions

In this work, we have presented a study of heavily oxygen-doped GaN films grown by MOVPE. For higher electron donor concentrations, $n > 10^{19} \text{ cm}^{-3}$, the formation of surface microcavities or micropits was observed. The pits were associated with oxide micro-precipitates. These studies indicate that the solubility of oxygen in GaN is limited by the formation of Ga_2O_3 -

Fig. 3. PL spectra of oxygen-doped and undoped samples at 20 K. Two DBEs transitions are shown with arrows for the sample grown with different oxygen partial pressures (see Table 1).

¹ Hexagonal shaped pits and clusters can be observed with the help of optical microscopy. The He–Cd laser beam was focused ($d \sim 20 \mu\text{m}$) both on the nearly pit-free regions (b in Fig. 4) and pit-clusters (a in Fig. 4).

Fig. 4. LT PL spectra of nearly pit-free (RK217a) and pit-covered (RK217b) surface of highly oxygen-doped ($2.9 \times 10^{19} \text{ cm}^{-3}$) sample. The spectra of an undoped sample (RK120) and a highly Si-doped sample (JG125) are shown for comparison.

related precipitates. Using spatially resolved PL measurements, these micropit regions were correlated with the 3.56 eV band due to free electron recombination in degenerate regions. These structural defects are likely responsible for the low mobility of the highly oxygen-doped layers.

Mn-related absorption and PL bands in GaN grown by metal organic vapor phase epitaxy

R.Y. Korotkov, J.M. Gregie, B.W. Wessels*

Department of Materials Science and Engineering and Materials Research Center, Northwestern University, Materials and Life Science Building, 2225 N. Campus Drive, Evanston, IL 60208-3108, USA

Abstract

In this paper, the optical absorption and photoluminescence spectra of semi-insulating Mn-doped GaN films were studied. Two characteristic bands were observed in the absorption spectra of Mn-doped epilayers at 300 K. The integrated intensities of these bands increased with increasing Mn concentration indicating that they were Mn-related. An analysis of the temperature behavior of the absorption band with a maximum at 1.5 eV indicated that it involved a free to bound transition from the valence band to the deep Mn-acceptor level. Photoluminescence measurements of Mn-doped films indicated the presence of an intra 3d-shell transition of the Mn ion. The luminescence band at 1.25 ± 0.02 eV is tentatively attributed to the $^4T_1(G) \rightarrow ^6A_1(S)$ transition. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Manganese has extensively been studied as a dopant in II–VI [1] and III–V [2,3] materials for optical applications [3]. The features of the optical spectra of Mn-doped films have usually been assigned to internal 3d-shell transitions within the Mn ion. The free Mn^{2+} ion with d^5 electron configuration has a 6S ground and a 4G first excited state [2]. A crystal field of trigonal symmetry in the wurtzite structure leads to the splitting of the 4G excited state into three states, 4T_1 , 4T_2 and 4A_1 , (from the lowest to the highest energy) [4–7]. The ground state of the Mn ion, 6A_1 , is unaffected by the crystal field. Therefore, a series of transitions including $^6A_1 \rightarrow ^4T_1$, $^6A_1 \rightarrow ^4T_2$ and $^6A_1 \rightarrow ^4A_1$ are often observed in absorption for Mn in wide gap hosts.

Manganese has been shown to form an acceptor level when it substitutes in the group-III metal site [2]. The binding energy of the Mn acceptor varies from 113 meV in GaAs to 400 meV in GaP and InP [2,3,8]. The binding

energies of Mn were found to follow a universal trend [9]. Caldas et al. indicated that the transition metal binding energies are referenced to the vacuum level and independent of the band edges of the host crystal [9].

The behavior of Mn in GaN has received limited attention [10]. However, electron paramagnetic resonance (EPR) studies of residual Mn impurities in GaN grown by the sublimation ‘sandwich method’ [11] and GaMnN grown by the ammonothermal method [12] unambiguously identified the presence of the $Mn^{2+} d^5$ ion. Furthermore, Raman scattering studies of GaMnN observed new bands around 300 and 667 cm^{-1} [12]. We previously reported our preliminary data on the absorption and PL spectra of deliberately Mn-doped GaN grown by metal organic vapor phase epitaxy (MOVPE) [13,14]. It was shown that Mn introduced two well-resolved characteristic absorption bands in the GaN thin films. In this paper, the optical properties of a series of GaN samples deliberately doped with Mn are reported.

2. Experimental

The MOVPE growth of Mn-doped GaN layers has been previously described [13]. Optical absorption–

reflection measurements at room temperature and in the 300–1200 nm range were performed using a Cary-500 spectrometer. Absorption spectra at 20–300 K were measured in the range 0.8–1.63 eV using a quartz halogen lamp and Zeiss monochromator with a resolution of 1.5 nm at 1 μ m. A Ge-detector was used to measure transmittance of the sample. All absorption spectra were normalized to account for the spectral responsivity of the lamp and Ge-detector as well as the monochromator. Transient PL decay curves were excited using 20 Hz, 4 ns pulses of N₂ laser with an excitation energy of 3.68 eV. The signal was detected using a Hamamatsu photomultiplier tube (R632) with a rise time of 9 ns.

3. Results and discussion

The normalized reflectance spectra of a series of undoped and Mn-doped samples at room temperature are shown in Fig. 1. The studied samples are reported in Table 1. It can be seen from Fig. 1 that in addition to the characteristic band gap absorption at 3.4 eV, observed in the undoped sample, two new well-resolved bands have been observed for the Mn-doped samples. The first band has a minimum at 1.5 ± 0.02 eV with a full width half maximum (FWHM) of 370 meV. The second band has an onset at 2.0 eV and a minimum at 2.8 ± 0.05 eV. Its asymmetrical shape indicates that it may be comprised of two separate bands. The absolute intensities of these two bands increase systematically with an increase of the Mn dopant, indicating that they are Mn-related.

Fig. 1. Room temperature reflectance spectra of undoped, and a series of Mn-doped samples (Table 1). Two new transitions at 1.5 and 2.9 eV observed in Mn-doped samples are labeled with arrows.

Table 1

Absorption coefficients and resistivities of undoped and Mn-doped films at $T = 296$ K

Sample #	Mn (μ mol/min)	Resistivity (Ω cm)	α (2.9 eV) (cm^{-1})	α (1.5 eV) (cm^{-1})
JG38	12.7	> 100	3688	1405
JG40	7.6	> 100	3232	1221
RK342	4.5	> 100	1076	330
RK326	Undoped	0.1	—	—

Fig. 2. Absorption coefficient as a function of energy for a series of undoped and Mn-doped samples listed in Table 1. The dashed line is a calculated fit using an ionization energy of 2.1 eV.

To determine the absorption coefficient of Mn-doped GaN films, polarized ($E \perp c$) transmission and reflection spectra were measured at 295 K. The absorption coefficient was calculated based on these measurements [13]. The dependence of the absorption coefficient as a function of energy for undoped and a series of Mn-doped epilayers is shown in Fig. 2. The maximum values of the absorption coefficient for the observed bands are also presented in Table 1. The nominally undoped GaN film is transparent in the visible region with the band edge absorption onset at $E_g \sim 3.42 \pm 0.02$ eV at room temperature. However, two absorption bands are formed in Mn-doped GaN. The first band has an onset at 1.4 eV and a maximum at 1.5 ± 0.01 meV. This band has an asymmetrical shape with an FWHM of 245 ± 10 meV. The second band is seen as a broad shoulder with an onset at 2.1 eV. This absorption occurs over a wide energy range (2.1–2.9 eV). The intensity of both bands systematically increased with Mn dopant as shown in Table 1.

The low temperature absorption spectrum of GaN:Mn was measured. The variation of the absorption band shape with temperature for the 1.5 eV band is shown in Fig. 3. At 20 K, a fine structure was resolved. We attributed the first sharp peak at 1.418 ± 0.001 eV to the zero-phonon line (ZPL) of the Mn free to bound acceptor transition, E_0 [14]. The fine structure at higher energies of the low temperature spectrum was attributed to coupling with two local vibration modes with energies of 20 and 73 meV. The observed fine structure is a characteristic feature of an absorption band involving a deep defect level and its phonon replicas [7,15].

With increasing temperature, however, the sharp peaks involved in the Mn-absorption band become less resolved, as seen in Fig. 3. Although the line shape changes, the total absorption intensity is approximately independent of temperature, such that as the intensity of the ZPL decreases the intensities of the side bands increase [7,15]. Therefore, the 'area conservation law', that is a characteristic feature of absorption involving a deep level, governs the behavior of the absorption spectrum at higher temperatures, as seen in Fig. 3. At room temperature a broad band (FWHM = 340 meV) is observed.

Based on the configuration coordinate analysis of the temperature-dependent behavior of the 1.5 eV band, it is concluded that this band involves a deep Mn-acceptor level, and not an internal 3d-shell transition. The position of this level is placed at 1.42 eV based on the ZPL. The level position with respect to the valence band is at $E_A = E_V + 1.42$ eV based on deep level optical spectroscopy measurements [14]. The threshold of the 2.1 eV band was independent of temperature (22 and 300 K), as seen in Fig. 4. Weak shoulders were also observed in the absorbance curve at 2.3 ± 0.05 and 2.7 ± 0.05 eV at $T = 22$ K.

Fig. 3. Absorbance spectra of the heavily Mn-doped film at different temperatures.

A broad PL band at 1.25 ± 0.02 eV was observed in Mn-doped samples [13]. The peak position of this band was independent of temperature. The transient decay curves obtained for the 1.25 eV band at different temperatures for one of the samples are shown in Fig. 5. The decay was exponential at low temperature. The calculated decay curve ($\tau = 7.8$ ms) is shown with a solid line in Fig. 5. A long decay time is a characteristic feature of forbidden transitions, such as $^4T_1 \rightarrow ^6A_1$ [2,6]. At high temperature, the decay time decreases and the decay curves become non-exponential. Similar behavior was observed for the Mn internal transitions in ZnS, where long decay times of 1.6 ms were measured [16]. In that case, the decay curve was non-exponential due to non-radiative recombination processes that become important at high temperatures for the Mn ion.

Fig. 4. Absorption spectra of the heavily Mn-doped films at 22 and 300 K.

Fig. 5. PL decay curves at 1.25 eV measured at different temperatures (RK342). The calculated exponential decay with a lifetime of 7.8 ms is shown with a solid line.

A proposed energy level scheme for Mn in GaN is as follows: the Mn-acceptor level is located at $E_v + 1.42$ eV. The observed higher lying absorption bands at 2.1 and 2.8 eV are tentatively associated with electron excitation from this level to the conduction band¹ and electron excitation from the VB to the first excited state (4T_1).^{2,3} The observed photoluminescence band at 1.25 eV is attributed to an intra d-shell transition from the first excited state to the ground state given as $^4T_1 \rightarrow ^6A_1$. Higher lying 3d excited states are believed to be degenerate with the conduction band and thus, are not observed in photoluminescence measurements.

4. Conclusions

The optical absorption and photoluminescence properties of semi-insulating Mn-doped GaN films were studied. Two characteristic absorption bands were observed in the spectrum of Mn-doped epilayers at 300 K. The integrated intensities of these bands increased with increasing Mn concentration, indicating that they were Mn related. An analysis of the temperature behavior of the absorption band with a maximum at 1.5 eV indicated that it involved a free to bound transition from the valence band to the deep Mn-acceptor level. Photoluminescence measurements of Mn-doped films indicated the presence of an intra 3d-shell transition of the Mn ion. The luminescence band at 1.25 ± 0.02 eV is tentatively attributed to the $^4T_1(G) \rightarrow ^6A_1(S)$ transition.

¹ This assignment assumes a large degree of compensation of the GaN, which is usually the case.

² The higher lying intra-ion transitions, $^6A_1 \rightarrow ^4T_2$ and $^6A_1 \rightarrow ^4A_1$ are likely to occur at 2.1 and 2.7 eV based on the observed transition in GaN:Fe³⁺ [5] absorption spectra, however, the intensity of these forbidden transitions has to be small. In contrast, large absorption coefficients were measured for the 2.1 eV band (Table 1), which were higher than that of the 1.5 eV band.

³ It is important to note, however, that several different states of Mn, such as Mn²⁺, Mn³⁺, Mn⁴⁺ can potentially introduce several deep levels in the band gap giving rise to several free to bound transitions as in Ref. [7].

Abstract

The Er³⁺ photoluminescence (PL) near 1.54 μm and PL excitation in Er-implanted GaN was investigated. We have found three different classes of optically active Er centers, with different excitation mechanisms. The majority of the incorporated Er ions can be excited only resonantly and the emission intensity decreases quite strongly with the temperature for high Er concentrations, due to excitation energy migration. The PL of centers dominating under above-band-gap illumination is mediated primarily by donor–acceptor pair recombination and has the same temperature dependence as the near-band-edge PL. We also find centers excited by broad, below-gap absorption bands, associated with deep traps, whose PL intensity is temperature independent. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Erbium doped semiconductors have been extensively studied over the last decade as a potential light source emitting at 1.54 μm , which is of great interest for optical fiber communication systems. As the emission is due to intra-4f-shell transitions, the lines are sharp and the wavelength is temperature insensitive, which makes the system particularly attractive. The drawback, however, is the strong temperature quenching of the emission intensity with decreasing band gap of the semiconductor host [1]. This has stimulated a wide interest in Er doping of GaN [2–4]. Visible and infrared electroluminescence of in situ Er doped GaN employing the impact excitation mechanism has been already achieved [5]. However, devices employing the much more efficient excitation channel involving electron hole pairs have not been reported yet. Such applications might be possibly realized on Er implanted GaN, as in this case the electron-hole mediated luminescence seems to be very

efficient. In this paper, we investigate Er-implanted GaN by means of photoluminescence (PL) and PL excitation spectroscopy and compare the efficiency and quenching behavior of different centers under direct and interband excitation.

2. Experiment

The samples used in this study were (i) nominally undoped and (ii) Mg doped GaN layers grown by MOCVD on Al₂O₃ substrates, as well as (iii) cubic, Mg doped GaN grown by MBE on GaAs substrates. All layers had a similar width of about 500 nm. The Mg doped samples had a room temperature hole concentration of 10^{17} cm^{-3} prior to implantation. Er was implanted at 800 keV into the undoped GaN/Al₂O₃ and at 300 keV into Mg doped GaN. The TRIM code estimated mean projected and straggling ranges were about 52 and 15 nm for 300 keV, 122 and 32 nm for the 800 keV implants, respectively. The estimated Er peak concentrations were about $2.5 \times 10^{18} \text{ cm}^{-3}$ in both GaN/Al₂O₃ samples and an order of magnitude lower in GaN/GaAs. The samples were subsequently annealed in

the temperature range of 900°C–1000°C in nitrogen gas flow for up to 30 min. Photoluminescence and PLE experiments were carried out in the temperature range of 5–300 K. The PL was excited with argon ion and tunable Ti:sapphire lasers, dispersed through a SPEX monochromator, and detected by a liquid nitrogen cooled Ge detector through a long pass filter with a cut-off at 1.2 μm . The spectra shown in the paper were typically taken at a power level of about 130 mW and at a spectral resolution of less than 0.1 nm. The data are not corrected for the detector and monochromator response.

3. Results and discussion

Low temperature Er^{3+} PL spectra measured for the GaN/ Al_2O_3 sample implanted with 800 keV Er ions are shown in Fig. 1. The spectra were obtained at three different excitation regimes: above band gap (351 nm), below band gap (514 nm), and resonant $^4\text{I}_{15/2} \rightarrow ^4\text{I}_{11/2}$ excitation (984.6 nm). In each case, the dominant emission comes from different Er centers. The broad PL line in the middle trace of Fig. 1 shows no structure even at a spectral resolution of 0.03 nm. Its shape does not change when varying the pump wavelength in the whole visible range of the Ar laser, indicating that the excitation does not proceed via intra shell transitions of Er but rather by a broad, trap-related absorption band. The dependence of the integrated PL intensity on pump

wavelength is shown in the inset. The emission under resonant Er excitation was found to be an order of magnitude less intense than that excited with above- and below-gap light, which is not surprising as the intra-4f transitions have very low absorption cross sections. The fact that none of the centers active under visible or UV can be excited resonantly indicates that the concentration of such centers is rather low.

Fig. 2 shows the PLE spectra taken at the detection wavelength of 1537.4 nm. At low temperatures (upper trace) the spectrum consists of many narrow lines which clearly belong to more than one center of different site symmetry. Though the relative intensities of the individual lines change with the detection wavelength no single Er center can be resolved. At elevated temperatures (>100 K), moreover, the PLE spectra for each detection wavelength become identical and additional PLE lines appear at lower wavelengths. At 300 K, they dominate in the excitation spectrum as shown in the middle trace of Fig. 2. This suggests that there is significant energy migration among different Er centers. In the lower trace of Fig. 2, the resonant transitions to the $^4\text{I}_{9/2}$ manifold can be seen, superimposed on a broad band showing a contribution from another type of Er center which is not excited resonantly but via a deep defect.

In the Mg doped sample grown on sapphire under above-gap excitation (see Fig. 3a), we observe the same

Fig. 1. PL spectra of 800 keV Er-implanted GaN recorded at 7 K for three different excitation regimes: above-band-gap (top), below-band-gap (middle), and intra-4f-shell (bottom). Excitation wavelengths are indicated. The inset shows integrated PL intensity as a function of the pump wavelength. The solid line is a guide for the eye.

Fig. 2. PL $^4\text{I}_{15/2} \rightarrow ^4\text{I}_{11/2}$ excitation spectra recorded at 7 and 300 K, and $^4\text{I}_{15/2} \rightarrow ^4\text{I}_{9/2}$ excitation spectra at 300 K in 800 keV Er-implanted GaN. The detection wavelength is 1537.4 nm.

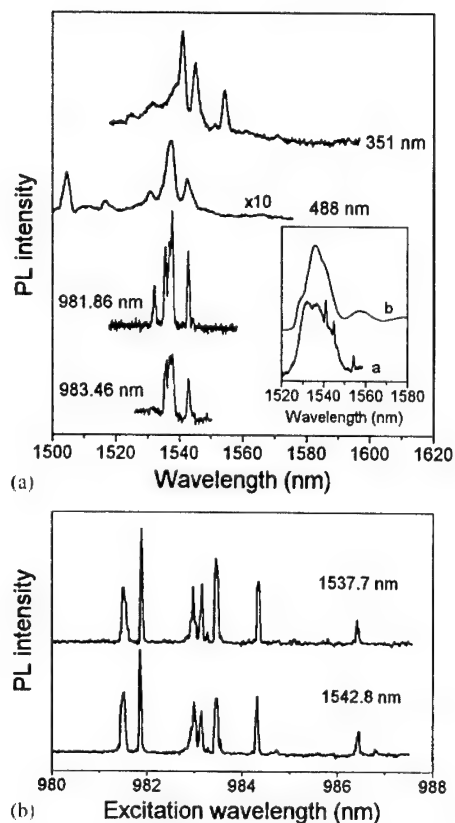

Fig. 3. PL (a) and PLE (b) spectra of 300 keV Er-implanted GaN:Mg/Al₂O₃ at various pump and detection wavelengths, at 6 K. The inset shows the PL spectrum excited at 351 nm with the beam focussed on a different spot (trace a) as compared to the PL of ErO_x precipitates in the bulk GaN:Er.

kind of luminescence as reported by Kim et al. [4], superimposed on a very broad background extending from a PL band peaked at about 700 nm. This band stems from implantation induced defects and appears also after Si implantation. Under excitation in the range of about 980 nm the defect related PL is no longer seen. The resonantly excited Er PL as well as the PL excitation spectra shown in Fig. 3(b) have extremely narrow line widths, indicating that the involved Er centers reside at sites with very little fluctuation of the crystal field potential. A similar, very weak PL spectrum (with some extra lines related to other centers) is also seen under the 488 nm pump wavelength. The Er distribution, however, is not uniform and if the exciting beam hits a different spot a very intense broad band appears, as shown in the inset of Fig. 3a. This band is identical to the one observed in bulk Er doped GaN grown at Unipress, which contained precipitates of a phase resembling Er oxide. In the Mg doped GaN/GaAs, we can also distinguish the PL of different Er centers under resonant and visible to UV pump wavelengths, with the most intense emission occurring for below-band-gap excitation.

Fig. 4. Temperature dependencies of the integrated PL intensity under excitation at 351 nm (diamonds), 514 nm (squares), and 984.4 nm (circles).

The temperature dependence of the luminescence intensity in the three excitation regimes is entirely different, as shown in Fig. 4 for the undoped GaN/Al₂O₃ sample. The PL intensity of Er centers excited with above gap illumination decreases with a deactivation energy of 95 ± 10 meV, which is responsible for the loss of intensity by almost half an order of magnitude at 300 K. The dominant excitation mechanism seems to be energy transfer from recombining donor–acceptor pairs and the deactivation energy is most probably related to the ionization energy of the shallower of the impurities involved. The other impurities must be deeper as we see no visible Er-related luminescence in any of the implanted samples. The PL intensity of Er centers excited via a broad, below-band-gap absorption band, in contrast, is thermally stable up to room temperature indicating that the traps mediating in the excitation process are much deeper. Surprisingly, centers excited directly into the 4f-shell show the strongest temperature quenching, with a smaller deactivation energy. This temperature quenching might be related to excitation energy migration at high Er concentrations as it is greatly reduced in the GaN/GaAs sample with an order of magnitude lower Er peak concentration.

4. Conclusions

The luminescence and luminescence excitation of Er-implanted GaN was studied. We found that Er excitation under above-band-gap illumination is mediated primarily by donor–acceptor pair recombination. This PL has a similar temperature dependence as that near the band edge. It was also found that direct excitation into the 4f-shell leads to a much more pronounced PL temperature quenching than any other excitation mechanism, which suggests that at the Er doping levels employed there might be considerable energy migration among the luminescent centers likely

to be excited by direct absorption. The most efficient excitation channel seems to be mediated via deep trap centers, introduced most probably by implantation. The extra advantage of such an excitation mechanism for possible applications in IR emitting LEDs is that the visible, competing Er luminescence is suppressed.

Abstract

We studied GaN grown by metal organic chemical vapour deposition (MOCVD) and molecular beam epitaxy doped with different Mg concentrations by photoluminescence, Hall and SIMS measurements. For the MOCVD samples, due to compensating deep donors a saturation of the hole density versus the Mg concentration is observed. These donors are also related to a 2.9 eV recombination observed in photoluminescence. Assuming that the compensating donors formed during growth processes involve nitrogen vacancies, hydrogen and a complex of both species, we are able to calculate the free hole concentration as a function of the Mg concentration for both growth methods. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Mg-acceptor; Compensating donors

1. Introduction

P-type conduction of GaN is typically obtained by doping with Mg, which acts as an acceptor. Typical values of the free hole concentration at room temperature (RT) are in the 10^{17} – 10^{18} cm⁻³ range. These values are sufficient for applications like light emitting diodes, but for others such as lasers, higher hole concentrations are desirable.

The high Mg acceptor binding energy and compensation effects, observed in the highly doped films, are the main reasons why higher values for the free hole concentration cannot be achieved. In GaN:Mg grown by MOCVD the additional effect of hydrogen has to be considered. In the as-grown state of the samples it passivates the incorporated Mg, and post growth treatments are needed for its activation [1,2]. The

molecular beam epitaxy (MBE) growth of GaN is hydrogen free, and the Mg acceptors are electrical active already in the as-grown state of the samples. Further, the compensation effects in MBE material are lower than in MOCVD material.

Theoretical calculations predicted that nitrogen vacancies (V_N) are the dominant compensating defects [3,4] in p-type GaN. Also experimentally this defect or complexes of it with Mg seem to be the most probable compensation centres [5,6].

We performed photoluminescence (PL), Hall and SIMS measurements on MOCVD and MBE grown GaN:Mg doped with different Mg concentrations. With the help of these experiments we were able to obtain information on the compensation and the presence of defects in the material. These informations are used to guide our calculations for the free hole concentration as a function of the Mg concentration. It turned out that the presence of hydrogen which mediates the V_N formation in MOCVD grown GaN:Mg is the important feature to explain the higher degree of compensation in these samples.

2. Experimental details

The experiments were performed on Mg-doped GaN epitaxial layers grown by MOCVD and MBE. A AlN buffer layer was used for the MOCVD samples, and a typical growth temperature is 1040°C [1]. The MBE samples were grown in an EPI 930 MBE system equipped with a radio frequency nitrogen plasma source. The growth temperature was 750°C [7]. The typical GaN layer thickness is 1 μm . For each sample the Mg doping concentration is determined by secondary ion mass spectroscopy (SIMS).

For the luminescence experiments, we used the 325 nm line of a HeCd (30 mW) laser as excitation source, and a grating monochromator in connection with a photomultiplier for detection. All the PL measurements were performed at 4.2 K in an Oxford bath cryostat.

Ohmic contacts in van der Pauw geometry were used for Hall-effect measurements.

3. Experimental results

The symbols in Fig. 1 show the experimental data of the free hole concentration as a function of the Mg concentration, for the MOCVD (full circles) and the MBE samples (full triangles).

For Mg concentrations up to $1 \times 10^{19} \text{ cm}^{-3}$, the free carrier concentration increases for both MOCVD and MBE samples. It roughly follows the linear increase expected from Fermi statistics. The scattering in data in this Mg concentration range is most likely caused by different concentrations of residual shallow donors such as O and Si. The typical concentrations of such species in MOCVD GaN are about $1 \times 10^{17} \text{ cm}^{-3}$.

For the MOCVD samples we observe for Mg concentrations above $1 \times 10^{19} \text{ cm}^{-3}$, first a saturation

Fig. 1. Triangles and circles corresponds to the free hole concentration versus the magnesium concentration, for MBE and MOCVD, respectively. Solid line shows the calculated data for MOCVD and the dotted line the calculated data for MBE.

and then a decrease of the free hole concentration. This is different to the MBE case where the hole concentration continuously increases. Obviously compensation effects are stronger in the MOCVD samples.

The PL spectrum (Fig. 2a) of low doped MOCVD films is dominated by the shallow donor to Mg acceptor recombination (violet band) with zero phonon line positioned at 3.27 eV. One can also see a band positioned at 2.9 eV (blue band). Increasing the Mg content, this blue band develops, and dominates the spectrum for high Mg doped films. For the highest doping concentrations the LO-phonon structure of this band is less pronounced and it red shifts to 2.8 eV. Investigating the excitation power dependence of this PL band we find that the emission maximum depends strongly on the excitation powers. Such behaviour is typical for compensated material with potential fluctuations arising from charged impurities.

For the MBE samples (Fig. 2b) the PL spectra show independent of doping a dominating shallow to Mg acceptor recombination at 3.27 eV. The 2.9 eV recombination is always of low intensity.

From the experiments it is likely that the defects participating in the blue recombination are also responsible for the saturation of the free hole concentration in MOCVD material, i.e. they are compensating donors. Based on temperature dependent PL measurements we ascribe the blue band to a recombination between compensating deep donors and shallow Mg acceptors. Similar conclusions were obtained by other authors [5,6,8].

Fig. 2. (a) PL of MOCVD grown GaN:Mg: (A1) low doped sample, (A2) medium/high doped sample and (A3) high doped sample. (b) PL of MBE grown GaN:Mg: (B1) low doped sample, (B2) high doped sample and (B3) line shape of the 2.9 eV recombination.

4. Calculations and discussion

The above described observations show that in highly Mg doped GaN grown by MOCVD, deep donors are needed to explain the compensation behaviour, as well as the appearance of the 2.9 eV recombination. Van der Walle proposed that nitrogen vacancies (V_N), hydrogen (H) and complexes of both (V_NH) are the relevant defects to be formed in p-type GaN. We have used his results on the Fermi level position dependent formation energies, to calculate free hole concentration as a function of the Mg concentration [3]. The formation of the Mg–H complex was not considered here. Neugebauer et al. [4] showed that the formation of this complex during growth is of minor relevance.

The density of compensating defects is calculated by the following equation:

$$N_D = N_S \exp\left[\frac{-E_{For}}{k_B T}\right], \quad (1)$$

where N_S is the number lattice sites for a defect ($4.4 \times 10^{22} \text{ cm}^{-3}$ for substitutional defects in GaN), T the growth temperature, k_B the Boltzmann constant and E_{For} the donor formation energy according to Fig. 3. Although these formation energies were basically extracted from [3], we have slightly fitted them ($\sim 100 \text{ meV}$) to obtain the best agreement with our experimental results. Entropy contributions were shown to be small and are not considered here [4].

The Fermi level (E_F) during growth is calculated by [9]

$$E_F = -k_B T \ln \frac{2\beta^{-1}(N_A - N_D)}{\beta^{-1}N_V\alpha + N_D + \sqrt{(\beta^{-1}N_V + N_D\alpha)^2 + 4\beta^{-1}N_V(N_A - N_D)\alpha}}, \quad (2)$$

where α is $\exp(E_A/K_B T)$ with E_A the acceptor binding energy (160 meV), β the valence band degeneracy factor, N_V the density of states for the valence band and N_A the acceptor concentration. By an iteration process one is able to find the values for N_D and E_F which satisfy both equations. For the calculations we assumed that residual

Fig. 3. Fitted formation energies for the three considered compensating donors. Lines a and b show the Fermi level position during growth (Mg concentration of $5 \times 10^{19} \text{ cm}^{-3}$) for MBE and MOCVD, respectively.

shallow donors are not present. By ignoring their existence we overestimate the free hole concentrations for low Mg concentrations. We further assume that the concentration of compensating donors stays constant during the cool down of the sample from growth temperature to RT. Finally, we are able to calculate free hole concentration as a function of the Mg incorporation by [9]

$$p = -\frac{N_D + \beta^{-1}N_V\alpha^{-1}}{2} + \sqrt{\beta^{-1}N_V\alpha^{-1}(N_A - N_D) + \left(\frac{N_D + \beta^{-1}N_V\alpha^{-1}}{2}\right)^2}. \quad (3)$$

Typical values for β and N_V are 3.6 and $3.2 \times 10^{19} \text{ cm}^{-3}$ at RT, 4.6 and $1.95 \times 10^{20} \text{ cm}^{-3}$ at 1000 K which is the growth temperature for MBE samples and 5.1 and $2.1 \times 10^{20} \text{ cm}^{-3}$ at 1300 K, the growth temperature for MOCVD.

In our calculations the information of growth technique enters in two different ways. The first one is the growth temperature, the second one is the hydrogen presence. For MBE we assume that hydrogen is not present thus only the formation of the nitrogen vacancy is considered. For MOCVD and in the presence of hydrogen the three defects, V_N , H and V_NH are of relevance. The low formation energy of the hydrogen centre (Fig. 3) plays here a central rule. In our calculations we find identical amounts of Mg and H centres to be present in as-grown MOCVD GaN:Mg.

P-type conductivity can be only reached when the hydrogen is removed which is done experimentally by a post-growth annealing treatment. For the calculations we assumed that all the H^+ centres are removed and that the V_NH^{2-} centres are transformed to the simple nitrogen vacancy defect. From the lines in Fig. 1 we can see a good agreement between the calculation and our experimental results for both MBE and MOCVD samples. As mentioned before, the deviation of the calculation to the experimental data for low doped samples is a result of ignoring residual shallow donor.

An important point that we can state from these calculations is that the main compensating centre for both growth techniques should be the nitrogen vacancy. This is supported by our PL results. The blue band is observed in MBE and MOCVD material at 2.9 eV. The red shift of the blue band, observed on some highly doped MOCVD grown samples, is related to band fluctuations which modify the peak position of the emission but do not change the structure of the involved

defects. Our calculations yield that the compensation ratio, i.e. the ratio between the concentrations of compensating donors and magnesium acceptors, is almost constant for the MBE samples ($\sim 3\%$). For the highly doped MOCVD samples the compensation can reach up to 20% which is also sufficient to account for the band fluctuations.

For the two growth methods the formation process of the V_N defect is different. In MBE it is directly formed, and in MOCVD it forms in addition by the intermediate V_NH complex. In fact the H incorporation and V_NH formation are essential to reproduce the strong compensation effect for the highly doped MOCVD samples. This effect could not be reproduced by assuming simply a higher growth temperature.

Some authors [10,11] reported that more than one compensating centre exists in MOCVD grown GaN:Mg. These centres could be related with remaining V_NH complexes or also, and especially at very high doping levels, with the V_NMg complex suggested by Kaufmann [5,6].

In summary our investigations show that the compensation effects observed in GaN:Mg grown by MBE and MOCVD can consistently be explained by the formation of V_N . The presence or absence of hydrogen

and the differences in growth temperature are sufficient to explain our experimental data.

Abstract

A comparison between unimplanted and annealed Ca implanted GaN samples was performed using PL and RBS techniques. Deep DAP recombination at 2.36 and 1.8 eV was found in both samples. New PL lines observed at 3.46, 3.368 and 2.59 eV in the implanted samples are discussed. Rutherford backscattering/channelling measurements reveal that 35% of Ca is located in substitutional Ga sites surrounded by complex defects. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Implantation; PL; RBS/C

1. Introduction

One of the major drawbacks of GaN based devices is the lack of suitable acceptors with lower ionisation energy than the 220 meV currently obtained with Mg doping [1]. In order to obtain controllable p-type conductivity, several workers studied the behaviour of potential acceptor species, for instance, Zn, Cd, Ca and Be, by in-grown doping or ion implantation [2–10]. While theoretical calculations predict for Ca_{Ga} an acceptor binding energy of 250–302 meV [11–13], temperature dependent Hall measurements showed that the ionisation level of Ca was 169 ± 12 meV [5]. Moreover, besides the previous work of Pankove [2], no other reports on photoluminescence (PL) studies were performed for Ca implanted samples.

In this work, we report PL studies in a set of Ca implanted samples with doses from 10^{13} to 10^{15} cm^{-2} . All the samples show, at room temperature, a similar green emission to the one previously observed by Pankove [2] and a broad red emission. Besides these two PL bands, both the emission band in blue and a structured near band edge (NBE) emission are observed at a low temperature. The PL bands were studied as a function of excitation density, time and temperature and

from these results, combined with X-ray emission (PIXE) and Rutherford backscattering/channelling analysis, the influence of Ca on luminescence as well as the contribution from optical active centres produced by annealing treatments is discussed.

2. Experimental

The wurtzite GaN layers were epitaxially grown on (0001)-plane sapphire substrates by MBE with a thickness of 1.5 μm . The Ca^+ ions were implanted either at room temperature or at 550°C with 180 keV and a fluence in the range from 5×10^{13} to $5 \times 10^{15} \text{ cm}^{-2}$. After implantation, the Ca samples were annealed at 1050°C for 15 min in flowing N_2 with a proximity cap. RBS/C analysis was carried out to determine the damage profiles and the lattice site location. The samples were mounted on a two-axis goniometer and channelling angular scans were performed along the [0001] and $[10\bar{1}1]$ directions [14]. The PL measurements were carried out with a 325 nm CW He–Cd laser and the excitation power density was typically less than 0.6 W cm^{-2} . A 325 nm band pass filter was used to attenuate laser lines other than the 325 nm line. PL was measured at temperatures between 14 and 300 K using a closed cycle helium cryostat. The luminescence was dispersed by a Spex 1704

E-mail address: tita@fis.ua.pt (T. Monteiro).

monochromator (1 m, 1200/mm) and detected by a Hamamatsu R928 photomultiplier. Excitation density was varied using a set of neutral density (ND) filters.

3. Results

In Fig. 1, a comparison between PL spectra of a 550°C implanted Ca^+ sample with $1 \times 10^{14} \text{ cm}^{-2}$ and annealed at 1050°C during 15 min and a virgin sample annealed under the same conditions is shown. The results reveal the excitonic lines at 3.485 and 3.453 eV in the virgin sample with full widths at half maximum (FWHM) of 26 and 6 meV, respectively. At lower energies, the PL of the unimplanted sample is dominated by broad emission bands in the blue (2.95 eV), green (2.36 eV) and red (1.8 eV). For the Ca implanted sample, a new emission line is observed at 3.46 eV as indicated by the arrow in the inset of Fig. 1. At lower energies, a strong narrow line with an FWHM of 4 meV is observed at 3.368 eV. Broad emission bands dominate the spectrum for lower energies, and as previously reported by Pankove [2] a strong green emission with a maximum at 2.5 eV is observed. Besides this emission band, the same broad bands were also observed in the unimplanted sample at 2.95 eV, 2.36 eV and 1.8 eV. The relative intensity of the emission bands is dependent on the laser spot position revealing that the luminescent defects are not uniformly distributed in the samples. The temperature dependence of PL is shown in Fig. 2. In the inset, the quenching of the 3.368 eV line is also

presented. Increasing temperature favours an inversion of the intensity of the 2.36 and 2.59 eV bands being consistent with a faster quenching for the 2.36 eV DAP. At room temperature, the green emission is peaked at 2.59 eV. The red 1.8 eV DAP presents a shift of 28 meV to higher energies with increasing temperatures.

In order to obtain information on the lattice site location of Ca, we performed detailed angular scans along the c -axis using the X-ray signal of Ca and Ga after annealing (Fig. 3). The curves show a minimum yield of 25% for Ga, while for Ca we have a value of 74%. Moreover, the Ca curve is now narrower than the Ga curve indicating that the Ca ions are displaced from the ideal Ga sites of the GaN lattice. This displacement is associated with the interaction of the Ca ions with defects present in its neighbourhood. According to the estimation [14]

$$f_{\text{sub}} = \frac{1 - \chi_{\text{min}}(\text{Ca})}{1 - \chi_{\text{min}}(\text{Ga})},$$

where f_{sub} is the fraction of impurity in substitutional sites, and $\chi_{\text{min}}(\text{Ca})$ and $\chi_{\text{min}}(\text{Ga})$ are the minimum yields at the channelling dips, we found a fraction of 35% of Ca in regular sites along the [0001] direction.

4. Discussion

The high energy spectrum of both samples are characterised by an NBE emission peaked at 3.485 eV due to the overlap of DX, FXA and FXB emissions

currently assigned in MBE samples near 3.475, 3.483 and 3.489 eV, respectively [15,16]. For the implanted samples, two new PL lines at 3.46 and 3.368 eV are observed at 14 K after Ca implantation. According to theoretical calculations, Ca in Ga sites is expected to introduce a deep acceptor level. If the 3.46 eV line could be assigned to an exciton bound to neutral Ca, then an acceptor level 230 meV above the VB is expected. Concerning the 3.368 eV line, it must be mentioned that it is quite similar in energy to the previously observed I_3 line currently assigned to strongly localised excitons associated with excitons bound to stacking faults [17–19]. As for the I_3 line, the 3.368 eV emission observed in the implanted samples shows an excitonic nature with the quenching processes being dominated by an activation energy of 17 meV. However, it is also known that the I_3 line is usually accompanied by an emission at lower energies (3.309 eV), the I_4 line [17–19]. In our samples this is not the case, no I_4 line is observed. Theoretical studies of the electronic structure of stacking faults in GaN have been recently reported [20,21] and they reveal the presence of an electronic level 0.13 eV above the VB. On the other hand, the authors of Ref. [21] pointed out that stacking faults can bound a quantum-well-like region of zinc-blende (ZB) material surrounded by wurtzite (WZ) host. The ZB/WZ interface exhibits a type-II line up with $\Delta E_v \approx 0.07$ eV and $\Delta E_c \approx 0.27$ eV. In order to clarify the nature of the 3.368 eV emission line in Ca implanted samples more work is under way.

Deep emission levels are currently observed in undoped and intentionally doped GaN samples giving rise to blue [22,23], yellow [24] and red [25,26] PL bands.

It is also known that annealing treatments considerably alter deep emission levels. Namely, two emission bands at 2.3 and 2.6 eV have been shown to be enhanced by annealing effects [27]. In our unimplanted sample, the recombination is dominated by two DAP emissions at 2.36 and 1.8 eV, consistent with previous observations in MBE annealed samples [27]. The 2.36 and 1.8 eV emissions are also observed in Ca implanted samples. The main features in the Ca implanted samples are these new lines at 3.46 and 3.368 eV as well as the broad emission band at 2.59 eV. While the 2.36 and 1.8 eV bands show a DAP character, the 2.59 eV band shows a supralinear dependence on excitation density and no shifts of the band maximum are observed with increasing delay times, temperature and excitation density. The band has no DAP character. Similar observations were found in MBE annealed samples [27] and by CL studies [22] where the emission was found to be homogeneously distributed with single columns and attributed to a complex defect involving point defects. If the 2.59 eV band is due to the same defects responsible for the emission observed in unimplanted samples [22,27] then the 29.5 meV found for the activation energy could be ascribed to the activation energy for non-radiative processes of the centre rather than the ionisation energy. However, at the moment it cannot be excluded that Ca would be involved in the defect that gives rise to the 2.59 eV band. It is known that Ca implantation into GaN samples causes lattice expansion and only a part of the implanted species occupies Ga sites [6–9] being electrically compensated due to the formation of complex defects with donor-like point defects, such as $\text{Ca}_{\text{Ga}}\text{-VN}$ and/or $\text{Ca}_{\text{Ga}}\text{-Ga}_\text{N}$ [8]. Assuming that the acceptor is compensated by the presence of a deep donor located ~ 600 meV below the CB, the emission at 2.59 eV could be explained by a defect–defect recombination between the deep donor and the 300 meV acceptor. A schematic model showing this hypothesis for the emission bands is depicted in Fig. 4.

Fig. 4. Schematic model for the recombination processes.

5. Conclusions

New excitonic lines, as well as a broad emission at 2.59 eV without DAP characteristics were found in Ca implanted GaN samples. One of the excitonic lines at 3.46 eV is tentatively assigned to Ca on Ga sites, because 33% of the Ca can be found in nearly substitutional Ga sites by RBS. If so, the acceptor level is located at 230 meV above VB. As the samples do not show a p-type conductivity, deep donors probably compensate the acceptors. In order to determine the nature of the 3.368 eV emission more work is under way. We mentioned that this line occurs similar to the energy in the I_3 line; however, the line is not accompanied by the I_4 line currently assigned to excitons bound to stacking faults.

Study of dopant activation in bulk GaN:Mg

R. Piotrkowski*, E. Litwin-Staszewska, T. Suski, I. Grzegory

High Pressure Research Center, Polish Academy of Sciences, Sokolowska 29/37, 01-142 Warsaw, Poland

Abstract

We have studied the time-dependent processes leading to the irreversible increase of conductivity in pressure-grown GaN:Mg. The analysis is based on a two-level model with a shallow ($E_v + 0.1$ eV) Mg-related acceptor level and a deep level at $E_v + 0.9$ eV. Our data indicate that the deep defect is present in all as-grown GaN:Mg samples and is generated in a large quantity by annealing above 600°C. The other process, which leads to the appearance of shallow Mg acceptors, is observed at temperatures as low as $\sim 300^\circ\text{C}$ and terminates below 600°C. From an analysis of the time dependences for both processes we found that the respective activation energies differ by a factor of 2. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Impurity and defect levels; Annealing; P-doping

Magnesium is practically the only acceptor impurity in Group-III nitrides. In most cases, however, it is electrically inactive in as-grown material and special annealing steps are required for obtaining efficient p-type conductivity [1]. Such Mg acceptor activation in MOCVD grown samples, which is achieved by annealing at temperatures 700–800°C, is attributed to the dissociation of Mg–N–H complexes. It was, however, pointed out that this temperature is much higher than that expected from the calculated energy of complex dissociation [2]. This means that additional information is needed to fully understand the mechanism of Mg activation processes.

With such motivation, we have studied thermally activated, time-dependent processes that lead to an increase of the p-type conductivity in bulk GaN:Mg. The crystals were grown under high N_2 pressure from Mg-rich Ga melt. The as-grown material has high resistivity due to the high background concentration of O donors which compensate the Mg acceptors. As we reported earlier [3], in this material an increase of Mg acceptor concentration is observed even at 300°C. Moreover, we indicated that in order to describe the

properties of the materials studied, a two-level scheme should be used. In addition to the shallow Mg acceptor, the deep level at $E_v + 0.9$ eV should be introduced. An important increase of deep state concentration was observed in the second annealing process between 600°C and 750°C.

In the present work, we concentrate on the kinetics of both annealing processes by analyzing the time dependences of resistivity measured during isothermal annealing. The details concerning crystal growth and sample preparation can be found in the previous paper [3].

In our experiment, we measured the sample resistivity, ρ , as a function of annealing time, at fixed temperature T_{ann} . The process of annealing was interrupted at certain moments and the dependence ρ vs. temperature was measured. The temperature in such measuring cycles was lower than T_{ann} , and the dependences $\rho(T)$ were reversible. Fig. 1 presents the results of such experiments for two GaN:Mg samples. The points on the left-hand side (Fig. 1a) show the sample resistivity decreasing with time during isothermal annealing. Those on the right-hand side (Fig. 1b) give the Arrhenius plots ρ vs. $(1/T)$ found in different points of annealing process. The evolution of the Arrhenius characteristics ρ vs. $(1/T)$ which is seen in Fig. 1b is typical for all samples studied by us. Initially, their slope (activation energy) is high and does not vary when the resistivity decreases during

Fig. 1. (a) Time dependence of resistivity measured for two GaN:Mg samples during isothermal annealing and (b) resistivity ρ vs. $1/T$ measured at different stages of annealing process. Arrows mark the interruption in annealing processes (a) during which the measurements shown in (b) were performed. Continuous lines in (b) are calculated using Eq. (1) (see Fig. 2). The lines in (a) are calculated using the fitting from Fig. 3.

annealing. At some point it changes to the low value characteristic for Mg acceptors, and then remains constant up to the end of the process. Such a surprising behavior is explained by the model analysis that follows.

As we have remarked in the preceding work [3], the electrical properties of samples in which the saturation of ρ was achieved by annealing at $\sim 500^\circ\text{C}$, are stable only below 600°C . Above 600°C , a decrease of sample resistivity with time is observed again. Also in this case, we have carried out the experiments identical to that in Fig. 1. The feature which now characterizes the evolution of the Arrhenius dependences ρ vs. $(1/T)$ is the downward shift of their high-temperature part. The activation slope remains unchanged being equal to about 0.5eV .

The analysis of the results is based on the solution of the neutrality equation for p-type conduction with two acceptor levels that are strongly compensated:

$$p + N_D = \frac{N_A}{1 + 1/g \exp((E_A - E_F)/kT)} + \frac{N_{A1}}{1 + 1/g \exp((E_{A1} - E_F)/kT)}, \quad (1)$$

where p is the hole concentration given by $p = N_v \exp(-E_F/kT)$. We denote by N_A and E_A the concentration and energy of shallow acceptors, N_{A1} and E_{A1} apply to deep centers and g denotes the degeneracy factor. N_D is the concentration of compensating donors assumed equal to $5 \times 10^{19} \text{ cm}^{-3}$, i.e. the concentration of oxygen atoms found by SIMS measurements.

In order to compare the results given by the solution of Eq. (1) with experiment, we calculated the resistivity

Fig. 2. Resistivity vs. inverse temperature $\rho(1/T)$ calculated in the model of two acceptor levels, heavily compensated by shallow donors ($N_D = 5 \times 10^{19} \text{ cm}^{-3}$). Curves are calculated for constant concentration of deep ($E_A + 900 \text{ meV}$) states $N_{A1} = 5.5 \times 10^{17} \text{ cm}^{-3}$ varying shallow acceptor concentration N_A which increases from the top to the bottom of the figure. (The energy E_A assumed equal to 110 meV .) The thick line corresponds to $N_A = N_D$.

as $\rho = 1/\sigma = 1/e\mu_h p$ with the single value of hole mobility $\mu_h = 5 \text{ cm}^2/\text{Vs}$ [3].

An example of the results given by such model calculations is shown in Fig. 2. The shown set of curves ρ vs. $(1/T)$ illustrates the evolution of the Arrhenius dependences when only the shallow acceptor concentration N_A is varied. In the upper part of Fig. 2, N_A is assumed to be lower than the shallow donor concentration N_D , while in the lower part $N_A > N_D$.

Comparing Fig. 2 with the experimental results in Fig. 1b clearly indicates that the low-temperature annealing process can be explained as increasing the

concentration of shallow acceptors when the concentration of deep centers does not change. For the case when only one level determines the hole concentration (i.e. far from line $N_A = N_D$ in Fig. 2), Eq. (1) reduces to a simpler form. As a result, in the lower part of Fig. 2, the approximate solution of Eq. (1) gives $E_F = E_A - kT \ln(g(N_A/N_D - 1))$. The hole density is then proportional to the quantity $\Delta N_A = N_A - N_D$ and becomes $p = N_v(T)g\Delta N_A/N_D$. This means that $\Delta N_A(t)$ can be determined from the measured dependence $\rho(t)$, once E_A is known. Similarly, in the upper part of Fig. 2 (above apparent diagonal) we have $E_F = E_{A1} - kT \ln(g(N_{A1}/N_{D\text{eff}} - 1))$. In this case, the effective concentration of donors $N_{D\text{eff}}$ which compensate deep centers is given by the difference $N_D - N_A$, i.e., ΔN_A has an opposite sign. Also, in this case, ΔN_A can be calculated from the measured resistivity. The (constant) magnitude of deep center concentration, N_{A1} , can be determined directly from the experimental dependences, ρ vs. $(1/T)$, if they have the form of two-slope curves similar to that shown for sample BIANCO12 (3 in Fig. 1b) or determined from best fitting.

The time variation of ΔN_A , calculated in the described manner from experimental $\rho(t)$ data, is shown in Fig. 3. Two curves correspond to the data from Fig. 2. The third relates to sample LINDA6 where annealing at 550°C does not change the slope of the Arrhenius plots. All the dependences in Fig. 3 are fitted to a function which is the sum of two exponentials

$$\Delta N_A(t) = A_0 + A_1(1 - \exp(-t/\tau_1)) + A_2(1 - \exp(-t/\tau_2)) \quad (2)$$

with two amplitudes A_1, A_2 of the same order of magnitude and a ratio $\tau_1/\tau_2 \approx 10$. The total amplitude

Fig. 3. Time variation of shallow acceptor concentration during low-temperature isothermal annealing, deduced from the measured R vs. time dependence. The continuous lines are fitted according to formula (2).

$A_1 + A_2$ corresponds to the increase of the effective concentration of Mg acceptors. As can be determined from Fig. 3, the greatest increase equals to $5.5 \times 10^{17} \text{ cm}^{-3}$. The hydrogen concentration found by the SIMS method for our samples is of the same order of magnitude. This makes plausible the hypothesis that the low-temperature annealing process is connected with the dissociation of complexes involving Mg–H pairs. Some additional experimental facts seem to indicate that the two exponential components that describe the kinetics really correspond to two processes, possibly involving Mg–H in different configurations (e.g. as described in Ref. [2]).

In the case of annealing at $T > 600^\circ\text{C}$, the resistivity decreases due to an increase in the concentration of deep centers, N_{A1} [3]. To determine the kinetics of this process, annealing data in two samples were analyzed.

This time the approximation used was $p = (N_v N_{A1}/g)^{1/2} \exp(-E_{A1}/2kT)$ derived from (Eq. (1)), when $N_{A1} \gg N_{D\text{eff}}$. In this manner we found that the final deep center concentration generated in the high-temperature process in the two samples measured at $T = 730^\circ\text{C}$ was equal to 6×10^{18} and $3.5 \times 10^{19} \text{ cm}^{-3}$ (the initial values of N_{A1} were about 10^{16} cm^{-3} – $5.5 \times 10^{17} \text{ cm}^{-3}$). The time dependences $N_{A1}(t)$ are exponential functions with the time constants reported in Fig. 4.

Fig. 4 is illustrated with the aim to get some idea as to how the presented results relate to Nakamura's process of Mg activation in MOCVD layers [1]. At first, we look for a simple model capable of reproducing the results of the isochronal annealing given in Ref. [1]. We found that such process should be characterized by a barrier of 2.85 eV. In Fig. 4, it is represented by the line 'N'. The points below this line represent the time constants for

Fig. 4. Time constants of annealing kinetics as a function of inverse temperature. The line N corresponds to the annealing process in MOCVD samples (Experimental data from Ref. [1] reinterpreted to obtain activation times—see text). H relates to high-temperature annealing. The points below N correspond to low temperature process. The line L passes through the data measured on sample Guardiola1.

isothermal *low-temperature annealing*, found for six GaN:Mg samples. (The longer times, which determine the duration of annealing, are shown). Although the speed of this process differs from sample to sample, the thermally activated character is clearly seen for the sample GUARDIOLA1 (open circles). This sample was annealed at several temperatures starting from 305°C which enabled us to determine the dependence of the time constant on temperature. As can be seen, it corresponds to the process activated with energy 1.67 eV (see the straight line 'L'). As concerns the *high temperature process*, the corresponding time constants lie above the line N. The activation energy for this process can be estimated to be 3.3 eV which corresponds to line 'H'.

In summary, we have studied the evolution of the electrical properties in the bulk GaN:Mg, caused by annealing at temperatures 300–750°C. The presence of two defect levels, compensated by shallow oxygen

donors, are confirmed in all samples. In particular, the deep $E_v + 0.9$ eV center is responsible for initial Fermi level pinning in untreated samples and at the beginning of low temperature annealing. The shallow acceptor levels of Mg are created (in relatively low quantity) during annealing at low temperature and can become dominant. The high-temperature annealing process has an activation barrier 2 times greater than that of the low-temperature one. It causes, however, the generation of an important number of deep centers.

Abstract

Magnetic resonance experiments, including optically detected magnetic resonance (ODMR) and electron paramagnetic resonance (EPR), have been performed on Si-doped homoepitaxial GaN layers grown by MOCVD and on high quality, free-standing ($\sim 200\text{ }\mu\text{m}$ -thick) GaN grown by HVPE. This allowed us to obtain information on the properties of native defects and dopants in GaN with a significantly reduced density of dislocations ($<10^7\text{ cm}^{-2}$) compared to that typically observed ($\sim\text{mid } 10^8\text{--}10^{10}\text{ cm}^{-2}$) in conventional heteroepitaxial GaN layers. The high structural and optical quality of the layers was revealed by cross-sectional TEM and detailed low-temperature photoluminescence (PL) studies, respectively. ODMR at 24 GHz on strong shallow donor–shallow acceptor recombination from the Si-doped homoepitaxial layer reveals evidence for Si or C shallow acceptors on the N sites. EPR of the new free-standing HVPE GaN confirms the low concentration of residual donors ($\sim 10^{16}\text{ cm}^{-3}$) as determined by Hall effect measurements. In addition, new deep centers are found from ODMR on the 2.4 eV “green” PL band and on the broad emission less than 1.8 eV from the HVPE GaN template. However, contrary to expectations, the reduction of random strain fields (associated with dislocations) has not led to significant changes in the character of the magnetic resonance (such as resolved electron-nuclear hyperfine structure) compared to that typically found for heteroepitaxial GaN layers. © 2001 Elsevier Science B.V. 1. Introduction

Dislocations are commonly thought to have a significant impact on the incorporation of impurities

and other point defects in GaN. Their influence on the electrical and optical properties of GaN and related alloys has been a subject of high interest. This includes their role as charged scattering centers and source of leakage paths in carrier transport in GaN materials and device structures [1,2]. Also, it has been suggested that radiative recombination processes such as the ubiquitous 2.2 eV “yellow” emission band occurs at or near dislocations [3].

The high levels of dislocations ($\sim\text{mid-}10^8\text{--}10^{10}\text{ cm}^{-2}$) typically found in conventional GaN heteroepitaxial layers are often thought to compromise the identification of residual defects and to influence the spin properties of dopants as investigated through magnetic

resonance techniques. For example, random strain fields associated with the dislocations can strongly influence the spin properties of shallow acceptors derived from degenerate or nearly degenerate valence band states. Also, as a source of additional broadening, these strain fields can render electron-nuclear hyperfine structure unobservable.

In order to explore these issues, low-temperature photoluminescence (PL), electron paramagnetic resonance (EPR), and optically detected magnetic resonance (ODMR) have been performed on homoepitaxial GaN layers grown by MOCVD and on high-quality, free-standing (thick) GaN grown by HVPE. This allowed us to obtain information on the properties of native defects and dopants in GaN with dislocation densities at least 2–3 orders of magnitude smaller than usually observed for GaN deposited on Al_2O_3 or 6H-SiC substrates. Several new defects are revealed from these studies, including evidence for either shallow Si or C acceptors on the N sites in the GaN homoepitaxial layers and for new deep centers in the HVPE-grown GaN. However, contrary to expectations, the reduction of random strain fields (associated with the dislocations) has not led to significant changes in the character of the magnetic resonance compared to that typically found for conventional heteroepitaxial GaN [4–7].

2. Experimental background

PL and ODMR experiments were performed on GaN homoepitaxial layers grown by MOCVD on the (0001) Ga face of (unintentionally doped) GaN bulk crystals. More details on the high pressure–high temperature synthesis of these crystals and the particular treatment of the surfaces prior to deposition of the CVD layers are provided elsewhere [8–9]. In this work the PL and ODMR from a 1 μm -thick Si-doped ($\sim 1\text{--}2 \times 10^{17} \text{ cm}^{-3}$) GaN homoepitaxial layer are highlighted. This film was deposited on top of 5 μm of undoped MOCVD-grown GaN. Cross-sectional TEM measurements revealed the high structural quality of these undoped and Si-doped homoepitaxial layers with dislocation densities $< 10^7 \text{ cm}^{-2}$. However, it is possible that the dislocation densities are significantly lower as observed from defect selective etching experiments [10] of similar homoepitaxial layers grown on these GaN bulk crystals.

PL, EPR, and ODMR were also performed on thick ($\sim 200 \mu\text{m}$) free-standing (n-type) GaN grown by HVPE after laser-assisted liftoff from the parent 2 in dia. Al_2O_3 substrate [11]. We note that the ODMR was obtained on PL from the top (growth-surface) side of this material which was mechanically polished and reactive ion etched. Recent X-ray, AFM, TEM, and Raman scattering measurements [11–14] all indicate the high crystalline quality of this HVPE GaN. In particular, similar to that

found for the GaN homoepitaxial layers, dislocation densities $< 10^7 \text{ cm}^{-2}$ were revealed by TEM images [11]. Furthermore, variable-temperature Hall effect measurements [12,15] on samples from the same wafer or ones similar to those investigated in this work revealed remarkably low levels of residual shallow donors ($\sim 7 \times 10^{15}\text{--}1.2 \times 10^{16} \text{ cm}^{-3}$) and compensating acceptors ($\sim 2\text{--}3 \times 10^{15} \text{ cm}^{-3}$) and, in addition, the highest low-temperature electron Hall mobilities ($\sim 8000 \text{ cm}^2/\text{Vs}$) attained to date in bulk GaN.

High-resolution PL was obtained at 5 K with the 325 nm line from a He–Cd laser. This emission was analyzed by a 0.85-m double-grating spectrometer and detected by a GaAs PMT. The PL between 1.3 and 3.3 eV was also obtained at 1.6 K under the same photoexcitation conditions as employed in the ODMR experiments. This PL was generated by the 351 nm line from an Ar^+ -ion laser ($\sim 1 \text{ W/cm}^2$), analyzed by a 0.22-m double-grating spectrometer, and detected by a Si photodiode. The 9.5 GHz EPR and 24 GHz ODMR spectrometers used in this work are described elsewhere [5].

3. Results and discussion

3.1. GaN homoepitaxial layers

As observed by other groups [16–18], high-resolution PL studies confirmed the high-crystalline quality of our undoped and Si-doped GaN homoepitaxial layers [19]. In particular, the Si-doped homoepitaxial sample exhibits sharper excitonic PL (linewidths $\leq 1 \text{ meV}$) compared to that reported previously for GaN grown on Al_2O_3 with similar Si doping levels [20]. The PL below 3.4 eV from the Si-doped homoepitaxial layer is shown in Fig. 1. Strong recombination at 3.26 eV and a series of LO phonon replicas ($E_{\text{LO}} \sim 92 \text{ meV}$) at lower energies are observed. This emission shifts monotonically to lower energies with decreasing excitation power densities ($\sim 11 \text{ meV}$ with P_{exc} reduced from 1 to 0.001 W/cm^2). Based on these characteristics and previous work [21], this PL is attributed to a recombination between shallow Si donors ($E_{\text{d}} \sim 30 \text{ meV}$) and shallow acceptors ($E_{\text{a}} \sim 220 \text{ meV}$). Likely candidates for the shallow acceptors will be discussed shortly. In addition, as invariably observed to some degree of strength in most n-type (as-grown or Si-doped) CVD GaN [5], a broad “yellow” PL band at 2.2 eV is also found. No additional emission was observed from this layer between 1.3 and 1.8 eV.

The ODMR obtained on the 2.2 eV PL band from the Si-doped GaN homoepitaxial layer with $\mathbf{B} \perp c$ is shown in Fig. 2. For comparison, ODMR on similar emission from (n-type) heteroepitaxial GaN reference layers grown on Al_2O_3 [5] and 6H-SiC [22] is also provided.

Fig. 1. PL obtained below 3.4 eV at 1.6 K from the Si-doped GaN homoepitaxial layer with $\sim 1 \text{ W/cm}^2$ of 351 nm radiation.

Fig. 3. ODMR obtained on the 3.26 eV SD-SA PL from the homoepitaxial GaN:Si film. The dashed curve is a two-component fit of the spectrum with \mathbf{B} 15° from the c -axis. The dotted line indicates the position of the SD resonance with \mathbf{B} near the c -axis.

Fig. 2. ODMR spectra found at 24 GHz on the 2.2 eV "yellow" PL bands from the Si-doped homoepitaxial GaN layer and heteroepitaxial GaN layers grown on Al_2O_3 and 6H-SiC (EM=effective-mass donor, DD=deep defect).

The lower signal-to-noise ratio of the ODMR from the homoepitaxial layer (as also seen in Fig. 3) relative to that found for the reference samples mainly reflects the degradation of the microwave cavity mode due to the high conductivity of the bulk GaN substrate. However, it is clear that the character of the ODMR observed on

this emission in the three cases is quite similar. Unfortunately, in spite of the reduced level of dislocations, no resolved hyperfine structure could be observed in the magnetic resonance of the homoepitaxial layer. The sharp feature (FWHM $\sim 2\text{--}3 \text{ mT}$) with $g_{\parallel} = 1.952$ and $g_{\perp} = 1.949$ is assigned to (effective-mass) shallow donors based on the previous work [4,5]. The shallow donors are likely Si on the Ga sites although residual O on the N sites may also contribute to part of this signal based on recent evidence for the shallow nature of O impurities in GaN [23]. Most groups agree that the broad resonance (FWHM $\sim 15 \text{ mT}$) with $g_{\parallel} = 1.989$ and $g_{\perp} = 1.992$ is associated with a deep defect (DD). We first ascribed this feature to deep donors based, in part, on the small negative g -shift with respect to the free electron g -value of 2.0023 [5]. However, from a magnetic resonance standpoint, the donor or acceptor character of this center is an open question based on the observation of similar g -shifts for one of the extremal g -values (i.e., g_{\perp}) associated with shallow Mg acceptors in GaN [24,25].

Representative ODMR found on the strong 3.26 eV SD-SA PL from the Si-doped GaN homoepitaxial film is shown in Fig. 3. Two luminescence-increasing signals are observed. The first feature (labeled SD) is again attributed to shallow donors based on the resonance

parameters (i.e., $g_{\parallel}, g_{\perp} \sim 1.95$). The second line (labeled SA) is only observed above the background for $\mathbf{B} < 45^\circ$ from the c -axis. However, if we take this limited data set and the usual expression for the g -values in the case of axial symmetry that describes most of the magnetic resonance observed to date in GaN (i.e., $g(\theta) = (g_{\parallel}^2 \cos^2 \theta + g_{\perp}^2 \sin^2 \theta)^{1/2}$, where θ denotes the angle between \mathbf{B} and the c -axis), the extremal g -values for this resonance are $g_{\parallel} \sim 2.1$ and $g_{\perp} \sim 1.99$.⁴ Most notably, this g -tensor is quite similar to that found from EPR and ODMR of shallow Mg acceptors in heteroepitaxial Mg-doped GaN [23,24]. For example, a comparison of the ODMR found on the SD-SA emission from the homoepitaxial layer with that observed on equivalent emission from a Mg-doped GaN/Al₂O₃ heteroepitaxial layer with $[\text{Mg}] \sim 2.5 \times 10^{18} \text{ cm}^{-3}$ (grown in a separate CVD reactor) is shown in Fig. 4. Thus, based on the similar character of the PL bands and the magnetic resonance, the broad ODMR feature on the 3.26 eV PL from the Si-doped homoepitaxial layer is assigned to shallow acceptors.

We note that Mg had never been introduced as a dopant source in the reactor employed for the growth of these homoepitaxial layers. Thus, we propose that likely candidates for the residual shallow acceptors are C or Si on the N lattice sites. The amphoteric nature of Si and C has been established for other III–V semiconductors such as GaAs [26]. In addition, recent PL work suggests that Si also introduces an acceptor level in GaN with E_a

of $\sim 220 \text{ meV}$ [27]. Thus, this feature (SA) is tentatively assigned to Si_N shallow acceptors, but we can not rule out C_N being responsible for all or part of this signal. Additional work is underway to identify this defect [19].

The apparent loss of the shallow acceptor resonance in the homoepitaxial layer for $\theta \geq 45^\circ$, perhaps due to severe broadening, is not understood at this time. We note, however, that similar intensity behavior and broadening (though not to the same degree) are often observed from magnetic resonance of (effective-mass) shallow acceptors and holes with highly anisotropic g -tensors (i.e., $g(\theta) = g_{\parallel} \cos(\theta)$, $g_{\parallel} \sim 2\text{--}4$, $g_{\perp} \sim 0$) associated with the $m_j = \pm 3/2$ (heavy-hole) valence band in other semiconductors such as bulk 6H-SiC [28] and CdS [29] and SiGe quantum wells under tensile strain [30]. For such states, any inhomogeneity in g_{\parallel} will lead to a pronounced broadening of the resonance when $g(\theta)$ is rapidly changing as is the case with $\theta \geq 45^\circ$.

Finally, we note that the nearly isotropic g -tensor associated with the shallow acceptors in the Si-doped homoepitaxial GaN layer is quite different than the highly anisotropic g -tensor expected (given above) for such centers in WZ GaN from effective-mass theory [31]. This likely reflects a symmetry-lowering local distortion of the shallow acceptors. Overall, the present results suggest that (a) the non-effective mass like character is not specific to Mg_{Ga} shallow acceptors and (b) random strain fields associated with high dislocation densities do not appear to be the major source of perturbation responsible for the nearly isotropic g -tensors observed for shallow acceptors in conventional heteroepitaxial GaN.

Fig. 4. Comparison of the ODMR observed on the SD-SA PL bands from a Mg-doped GaN/Al₂O₃ sample (from Ref. [24]) and the Si-doped GaN homoepitaxial layer. The emission from the Mg-doped GaN layer was analyzed through a 0.22 m double-grating spectrometer.

3.2. Free-standing (thick) HVPE GaN

Though not nearly as sharp as the excitonic PL observed from undoped GaN homoepitaxial layers with linewidths of $\sim 0.1 \text{ meV}$ [16–19], the bandedge emission from these free-standing (thick) HVPE GaN templates is characterized by linewidths less than 1 meV [14]. An example of a high-resolution PL spectrum obtained at 5 K that demonstrates the high crystallinity of this material is shown in the inset of Fig. 5. Both impurity-bound and free exciton lines are observed between 3.46 and 3.52 eV [14]. The PL below 3.3 eV from this sample is also shown in Fig. 5. Most notably, instead of the 2.2 eV “yellow” PL band, a broad “green” emission band at 2.4 eV is found. Recent lapping studies [13] of these templates with $\sim 15 \mu\text{m}$ removed from the

⁴We note that the highly anisotropic expression expected for the g -tensor (i.e., $g(\theta) = g_{\parallel} \cos(\theta)$, $g_{\perp} \sim 0$) of effective-mass shallow acceptors in WZ GaN (as found for shallow acceptors in other semiconductors with similar hexagonal crystal symmetry such as 6H-SiC and CdS) does not describe the g -values of this resonance.

Fig. 5. PL spectrum obtained below 3.3 eV at 1.6 K from the free-standing HVPE GaN template. The small dip near 1.8 eV is a grating response. Inset: high resolution PL found at 5 K in the near-bandgap spectral regime (from Ref. [14]).

damaged back surface indicate that this emission is intrinsic to the bulk material (i.e., not a result of the post-growth treatment). One group has proposed that isolated Ga vacancies (V_{Ga}) or V_{Ga} -related complexes are involved in this “green” PL [32]. In addition, as typically observed from HVPE-grown GaN [33,34], this sample exhibits weak, broad emission between 1.4 and 1.8 eV (referred to as the “red” PL band).

A representative EPR spectrum obtained for the 170 μm -thick GaN template with $\mathbf{B} \perp c$ is shown in Fig. 6. The EPR for a 10 μm -thick HVPE-grown GaN/ Al_2O_3 reference sample with $n_{300\text{ K}} \sim 1 \times 10^{17} \text{ cm}^{-3}$ is also shown for comparison. Single lines with g_{\parallel} , $g_{\perp} \sim 1.95$ are found and ascribed to shallow donors as discussed earlier. Most notably, the density of spins associated with the signal from the Samsung sample is estimated to be $\sim 6 \times 10^{15} \text{ cm}^{-3}$ ($\pm 50\%$) from a comparison with the EPR of a P-doped Si standard. This density is in good agreement with the concentration of uncompensated shallow donors ($N_{\text{D}} - N_{\text{A}}$) determined from variable-temperature Hall effect measurements of samples from the same 2 in.-dia. wafer.

Unfortunately, additional structure was not revealed in the EPR of the Samsung HVPE GaN. In fact, due to a lower concentration of donors, this sample exhibits a broader EPR linewidth (FWHM ~ 27 G) compared to that found for the more highly conducting GaN/ Al_2O_3 layer (FWHM ~ 12 G) due to unresolved hyperfine structure between the spin of the (isolated) donors and the host lattice nuclei. This interaction is “averaged” out for GaN with larger concentrations of interacting

Fig. 6. EPR spectra obtained at 9.5 GHz for two HVPE-grown GaN samples. Top: free-standing GaN template ($n_{300\text{ K}} \sim 1 \times 10^{16} \text{ cm}^{-3}$). Bottom: GaN/ Al_2O_3 reference; $n_{300\text{ K}} \sim 1 \times 10^{17} \text{ cm}^{-3}$.

donors [35] as found in the 10 μm -thick HVPE GaN/ Al_2O_3 sample.

ODMR obtained on the 2.4 eV “green” PL band is shown in the top half of Fig. 7. As also found on the 2.2 eV “yellow” PL emission, the resonance labeled EM is assigned to effective-mass (shallow) donors. The second resonance, labeled A_1 , is new. It exhibits a strong intensity anisotropy with $g_{\parallel} = 1.975$ and $g_{\perp} = 1.969$. The g -values suggest a donor-like defect but the (axial) intensity anisotropy is more often found for acceptor-like defects associated with degenerate or nearly degenerate valence band states. Thus, though more work is clearly needed, we tentatively assign this feature to a deep acceptor of unknown origin. In addition, the g -tensor and intensity behavior of this center are quite different compared to that found for the deep defects (i.e., $g_{\parallel} = 1.989$ and $g_{\perp} = 1.992$) involved in the 2.2 eV “yellow” PL [5–7,22]. This indicates that these centers are of different origin.

ODMR found on the PL less than 1.8 eV is shown in the bottom half of Fig. 7. Two luminescence-increasing signals are observed. The first line at ~ 870 mT is again attributed to shallow donors. The second feature (labeled A_2) is also new. It is isotropic with $g = 2.019$ and a FWHM of ~ 25 mT. This signal is assigned to deep acceptors based on these magnetic resonance parameters and the near-midgap PL. We note that this defect is different than the deep center with $g_{\parallel} = 2.008$

Fig. 7. ODMR found on the 2.4 eV “green” PL band and near-IR emission from the free-standing HVPE GaN sample. The features labeled A_1 and A_2 are tentatively assigned to acceptor-like defects.

and $g_{\perp} = 2.004$ revealed by ODMR on similar near-IR emission from other HVPE-grown GaN [25,36].

4. Summary

ODMR and EPR experiments have been performed on Si-doped homoepitaxial GaN layers grown by MOCVD and on free-standing (thick) GaN grown by HVPE. The high structural and optical quality of these materials was revealed by cross-sectional TEM and low-temperature PL studies, respectively. ODMR reveals several new defects, including evidence for either Si or C shallow acceptors on the N lattice sites in a Si-doped GaN homoepitaxial layer and for two new deep centers in the HVPE-grown GaN templates. In addition, EPR confirmed the low concentration of residual donors in these free-standing layers. The reduced dislocation densities, however, has not led to significant changes in the character of the magnetic resonance (such as resolved electron-nuclear hyperfine structure) compared to that found previously for conventional heteroepitaxial GaN. However, we suggest that the application of more sophisticated magnetic resonance techniques such as electron-nuclear double resonance (ENDOR) or optically detected—ENDOR should be pursued for identification of defects in these more pure GaN materials.

Abstract

The electrical properties of the n-GaN and n-InN, subjected to proton irradiation, are studied. The irradiation of the n-InN results in an increasing concentration of charge carriers, whereas strong compensation effects take place in the proton-irradiated n-GaN. The annealing behavior of the radiation-induced defects in both materials is discussed briefly. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Interest in experimental studies of the point defects in the GaN produced by irradiation with fast electrons and protons is steadily growing in the hope to obtain an understanding of the complex nature of native and impurity-related defects in this material; see for instance Refs. [1–6]. The situation for the irradiated InN layers is even worse, since the properties of the point defects in the InN are so far unknown.

The purpose of the present work is to investigate the production and annealing processes of the proton irradiation-induced defects in the n-GaN and n-InN.

2. Experimental

Layers of hexagonal n-GaN and n-InN on (0001) sapphire substrates were grown by the MOCVD and plasma-assisted MBE techniques, respectively. The

crystal structure of the layers were well characterized by X-ray diffraction and Raman spectroscopy. The layer thickness ranges from 1.0 to 1.5 μm . The as-grown n-InN layers were nominally undoped, with electron concentrations in the low 10^{20} cm^{-3} . In some cases, Mg or Dy impurities were added during growth for reducing the free electron concentration. Auger spectroscopy did not reveal any significant content of oxygen in the n-InN layers.

Samples were irradiated with protons of 150 keV. After irradiation, the samples were subjected to isochronal annealing in steps of 50°C or 100°C for 20 min in nitrogen.

Hall effect and conductivity measurements were carried out using the Van der Pauw technique. The Raman scattering measurements were taken at room temperature.

3. Results and discussion

In Figs. 1 and 2, several typical dependencies of the electron concentration and mobility, $n(T)$ and $\mu(T)$, in one of the n-InN layers are shown. As can be seen from

Fig. 1. Electron concentration versus reciprocal temperature in the n-InN counterdoped with Mg before the irradiation (open circles), after the proton irradiation (solid circles), and after annealing at $T = 300^\circ\text{C}$ (solid triangles). The irradiation dose, $\Phi = 1 \times 10^{16} \text{ cm}^{-2}$.

Fig. 2. Electron mobility versus temperature in the n-InN counterdoped with Mg before the irradiation (open circles), after the proton irradiation (solid circles), after annealing to $T = 300^\circ\text{C}$ (solid triangles down), $T = 450^\circ\text{C}$ (solid triangles up), and $T = 500^\circ\text{C}$ (solid diamonds). The irradiation dose, $\Phi = 1 \times 10^{16} \text{ cm}^{-2}$.

Fig. 1, proton irradiation results in a substantial increase in the concentration of the charge carriers. This effect was observed for all the samples, independent of the counterdoping. Evidently, the increase in the electron concentration in the n-InN after the irradiation is due to

the production of radiation-induced defects with shallow donor states. The production rate is the same, about $2 \times 10^4 \text{ cm}^{-1}$, over a wide dose range from 1×10^{15} to $1 \times 10^{16} \text{ cm}^{-2}$. All these experimental facts suggest that these defects are native. We believe that the native defects responsible for the net effect in the irradiated n-InN can be attributed to immobile nitrogen vacancies.

Up to $T = 100^\circ\text{C}$, there is no change in the $n(T)$ and $\mu(T)$ curves. A pronounced decrease in $n(T)$ by 30% was observed over a temperature interval of $T = 250\text{--}300^\circ\text{C}$; see Fig. 1. At this annealing stage, the annealed fraction of the electron mobility reached nearly 50%, as can be estimated from Fig. 2. At elevated temperatures, the annealing behavior of defects becomes rather complicated. First, a reverse annealing stage of the electron concentration and mobility takes place in the temperature interval from $T = 400^\circ\text{C}$ to 450°C . As a result, the concentration of charge carriers returns practically to the value measured in the irradiated n-InN and the mobility drops by an order-of-magnitude; see Fig. 2. After annealing to $T = 500^\circ\text{C}$, the $n(T)$ curves were found to be little affected but the electron mobility became much higher than that in the non-irradiated layers.

In accordance with the earlier observations [7], in Raman spectra of as-grown n-InN layers we also revealed the presence of a band at $\nu = 590 \text{ cm}^{-1}$; see Fig. 3. This band has been attributed to the L^- -LO mode of Raman scattering. Our study of the proton-irradiated n-InN clearly showed that the intensity of this band is dose dependent; see Fig. 3. Theoretical calculations of the cross-sections for three different models made it possible to conclude that the Raman scattering in the region of interest is associated with the short-range potential scattering process due to the presence of defects; see Fig. 4. As is seen in Fig. 3, the proposed model gives a satisfactory explanation to the experimental data. Details of calculations will be discussed in a separate paper.

Contrary to the n-InN, the proton irradiation of the doped n-GaN:Si leads to a substantial decrease in the concentration of the charge carriers; see Figs. 1 and 5. The electron removal rate estimated from the $n(T)$ curves given in Fig. 5 is about $1 \times 10^4 \text{ cm}^{-1}$. Surprisingly, the electron removal rate in the n-GaN:Si with a lower doping level is evidently smaller, at least by a factor of 3; see Fig. 5. It has been reported [1,6] that in the doped n-GaN:Si subjected to fast electron irradiation, the defect production rate is dependent on the doping level, too.

There are no significant changes in the $n(T)$ dependencies after the annealing of the proton-irradiated n-GaN to $T = 200^\circ\text{C}$, whereas the electron mobility decreases noticeably. The first annealing stage of defects takes place over a temperature interval of $T = 300\text{--}400^\circ\text{C}$. As is seen from Fig. 6, the mobility of the charge

Fig. 3. The experimental and calculated Raman spectra in the n-InN before the irradiation (curve 1), after the proton irradiation at $\Phi = 5 \times 10^{15} \text{ cm}^{-2}$ (curve 2), and $\Phi = 1 \times 10^{16} \text{ cm}^{-2}$ (curve 3). Calculated spectra are shown by the broken line. The probability of the short-potential scattering process due to the defects is assumed to vary proportionally with the defect concentration. The ratios of the intensities of the E_2 and LO bands are given. The E_2 band is used as a reference, since its intensity is not sensitive to the presence of the defects.

Electron concentration versus reciprocal temperature in the heavily doped n-GaN:Si before the irradiation (open circles), after the proton irradiation (solid circles), and after annealing at $T = 400^\circ\text{C}$ (solid triangles up) and $T = 600^\circ\text{C}$ (solid triangles down). The irradiation dose, $\Phi = 1 \times 10^{14} \text{ cm}^{-2}$. For comparison purposes, two $n(T)$ curves for the moderately doped n-GaN:Si before the irradiation (crosses) and after the proton irradiation at the same dose (open triangles up) are also shown.

Fig. 6. Electron mobility versus temperature in the n-GaN:Si before the irradiation (open circles), after the proton irradiation (solid circles), after annealing at $T = 400^\circ\text{C}$ (solid triangles up) and $T = 600^\circ\text{C}$ (solid triangles down). The irradiation dose, $\Phi = 1 \times 10^{14} \text{ cm}^{-2}$.

tially. The mobility of the charge carriers becomes even larger than that in the initial n-GaN. After annealing at $T = 700^\circ\text{C}$, the fraction of unannealed defects turned out to be between 20% and 30%.

4. Conclusions

The behavior of defects in the n-GaN and n-InN produced by proton irradiation and subsequent annealing has been studied. From the data obtained on the n-InN it can be concluded that most likely the nitrogen vacancies with shallow donor states are responsible for the increasing concentration of free electrons in the irradiated n-InN. It has been demonstrated that in the Raman spectra, the intensity of a band at $\nu = 590\text{ cm}^{-1}$ in the proton-irradiated n-InN layers is dose-dependent. Theoretical calculations showed that the model of defects with short-range potential gives a satisfactory explanation for this band in Raman scattering. The first stage of defect annealing in the irradiated n-InN takes place at $T = 300^\circ\text{C}$.

The production rate of native defects in the irradiated n-GaN appears to be Fermi-level dependent. Two main recovery stages of the electron concentration over two intervals from $T = 300^\circ\text{C}$ to 400°C and from $T = 500^\circ\text{C}$ to 600°C have been found.

A radiation-produced defect in GaN displaying hyperfine structure with three Ga atoms

G.D. Watkins*, L.S. Vlasenko¹, C. Bozdog

Department of Physics, Lehigh University, 16 Memorial Drive East, Bethlehem, PA 18015-3182, USA

Abstract

Electron-irradiation of undoped n-type GaN with 2.5 MeV electrons at room temperature produces a broad PL band at ~ 0.95 eV, and an $S = 1/2$ ODEPR center, labeled L1, is observed in it. The L1 signal reveals partially resolved structure, which can be matched accurately as arising from hyperfine interaction with three equivalent Ga atoms. Irradiation in situ at 4.2 K produces the 0.95 eV band but the L1 ODEPR signal emerges only upon subsequent annealing at room temperature, as another ODEPR signal identified as interstitial Ga disappears. The possibility that both L1 and the 0.95 eV PL arise from the Ga vacancy is discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; ODEPR; Ga interstitial; Ga vacancy

1. Introduction

Vital to successful device application of any semiconductor material is the understanding of its intrinsic defects, because they provide various diffusion mechanisms involved in processing and device degradation, as well as in often controlling background doping and compensation. In GaN, little is presently known concerning the properties of its isolated vacancies and interstitials.

The only direct and unambiguous method of introducing vacancies and interstitials for experimental study is by high-energy electron irradiation, where host atoms can be displaced from their lattice sites by Rutherford scattering. In addition, the only truly successful experimental technique for identifying and studying the defects has proven to be electron paramagnetic resonance, detected either directly (EPR) or optically (ODEPR). Studies combining electron irradiation and ODEPR have recently begun in GaN [1,2], and already the isolated interstitial Ga atom has been identified [3].

Here, we describe such further studies, in which a second defect produced by the irradiation, labeled L1, is described. The possibility that it is the isolated Ga vacancy is discussed.

2. Room-temperature electron irradiation

The results reported [1] for room-temperature irradiation of undoped (n-type) GaN by 2.5 MeV electrons can be summarized as follows: In all the samples studied (MOCVD, MBE, and HVPE), the irradiation was observed to cause a substantial decrease in the visible and band-edge luminescence, while two new bands were produced in the near infrared—a sharp zero phonon line at 0.88 eV with associated phonon structure, and a broader overlapping band centered at ~ 0.95 eV. An $S = 1$ ODEPR signal, labeled L2, was seen only in the 0.88 eV system, while in the 0.95 eV band, three new ODEPR signals, labeled L1, L3 and L4 were observed. Of particular interest in these studies were L3 and L4 because each displayed well-resolved hyperfine interaction (hf) from a single Ga nucleus, suggesting an involvement of some kind for an interstitial Ga atom.

In the present paper, we turn our attention to L1. We find that it also carries important hf information, as

Fig. 1. (a) ODEPR spectrum of L1, and (b) its second derivative, for $\mathbf{B} \perp \mathbf{c}$, compared to predictions for hf interaction with three equivalent Ga atoms.

revealed by partially resolved structure, as shown in Fig. 1. A simulation of the structure assuming hf interaction with *three equivalent Ga nuclei* is also shown. In this simulation, the sticks represent the relative intensities and predicted positions for each of the lines that would arise from three identical $I=3/2$ Ga nuclei (60% ^{69}Ga , 40% ^{71}Ga , with $^{71}\mu/^{69}\mu=1.2706$) and with a 100 MHz hf interaction for the ^{69}Ga $I=3/2$ nucleus. These sticks were convoluted with a single Gaussian of appropriate width in order to give the dashed curves, which match, remarkably with the structure and overall line shape, both of the spectrum and of its second derivative. The hf splitting appears isotropic, with no distinguishable difference (± 10 MHz) vs. the orientation of \mathbf{B} . Comparison of the measured 100 ± 10 MHz hf value with estimated values for the free ^{69}Ga atom [4], indicates that somewhere between 1.4% and 5% of the wavefunction is accounted for on each of the Ga atoms. (1.4% 4s character accounts for the isotropic part. The additional 3.6% allows for a maximum 4p contribution, reflecting an upper estimate for possible hf anisotropy of <16 MHz.)

3. Electron irradiation at cryogenic temperatures

Before we consider possible defect models that might account for the three-Ga structure, let us first consider what we have learned concerning its formation. For this, we consider our more recent results for irradiation in situ at 4.2 K. As we have previously briefly reported [3], immediately after a low-temperature irradiation, the broad 0.95 eV PL band is present, but the 0.88 eV system is absent. However, none of the ODEPR signals present after room temperature irradiation (L1, L2, L3, L4) are observed. Instead, a new ODEPR signal is observed in

the 0.95 eV band, labeled L5, which we have identified as arising from the isolated interstitial Ga atom, as evidenced from its strong, well-resolved, Ga hf structure. Both this, and an accompanying ODEPR signal from the residual shallow donor, are negative, revealing a spin-dependent transfer process of an electron from the donor to paramagnetic Ga^{2+} , which competes with the 0.95 eV PL process. L5 is stable up to room temperature, at which point it decreases with an apparent time constant of several hours. Over this same time period, the 0.88 eV system emerges with its associated L2 ODEPR, as does L1, which is detected in the remaining 0.95 eV band. (Substantial loss of the 0.95 eV band also occurs during the room temperature annealing, but approximately $\sim 10\%$ of its original intensity immediately after the 4.2 K irradiation remains, and is stable, along with the L1 signal up to $\sim 600^\circ\text{C}$.)

From the disappearance of the interstitial Ga signal at room temperature, we conclude that it is mobile at this temperature. The simultaneous emergence at this temperature of the L1 spectrum, as well as the 0.88 eV PL band and its associated L2 ODEPR spectrum, strongly suggests that each may result directly or indirectly from the migration and trapping of the Ga interstitial.

Another important observation that must be factored into our modeling is that the broad 0.95 eV PL band is present immediately after the 4.2 K irradiation. It, therefore, must arise from an intrinsic defect itself. Although 90% of it is lost after room temperature annealing, the remaining component is stable to $\sim 600^\circ\text{C}$. L1 continues to be detected in it, disappearing with it at 600°C .

4. Models

The three equivalent Ga-atom hyperfine structure of L1 suggests three possibilities, which are illustrated in Fig. 2.

4.1. Trapped N vacancy

In Fig. 2(a), we show a nitrogen vacancy, which is missing one of its Ga nearest neighbors. This could result, as shown, from trapping of the vacancy by an impurity (X) on the Ga sublattice. Since the nitrogen vacancy is believed to be a shallow donor, a logical impurity might be a Group-II atom such as Mg, or Zn, each of which is an acceptor. With only a low-abundance nuclear spin isotope in either case, only the three remaining Ga atom neighbors would contribute to the structure.

Fig. 2. Structural models for L1: (a) trapped N vacancy, (b) trapped Ga vacancy, (c) Jahn-Teller-distorted isolated Ga vacancy.

4.2. Trapped Ga vacancy

In Fig. 2(b), we show a Ga vacancy trapped next to an impurity (X) on the nitrogen sublattice. A logical trap might be a substitutional group-VI atom donor, such as the common impurity oxygen, which experiences a Coulomb attraction to the negative Ga-vacancy deep acceptor. In this case, the three Ga neighbors could be the three near neighbors back-bonded to the impurity atom, as shown. In such a model, the dominance of the Ga hf interactions over those of the three nitrogen near neighbors to the vacancy is helped by ~ 5 times greater Ga atomic hf values over those for N. The total concentration of the wavefunction required on the three Ga's, only between 4% and 15%, is reasonable. At the same time, the nitrogen hf contributions could provide the major remaining broadening. As in the case for a group-II atom above, group-VI atoms also have low-abundance magnetic nuclei, and would not contribute to the hf structure.

4.3. Isolated Ga vacancy

In Fig. 2(c), we show a distorted Ga vacancy in its paramagnetic V_{Ga}^{2-} charge state. Here, the inward distortion of the on-axis nearest neighbor nitrogen serves to shift some of the spin wavefunction onto its back-bonded three Ga neighbors, which could supply the observed hf interactions. We can expect such a Jahn-Teller distortion for the paramagnetic V_{Ga}^{2-} charge state because in cubic GaN, it would be degenerate with one hole in its t_2 vacancy orbital [5]. (It is isoelectronic to the V_{Zn}^- defect in cubic ZnSe, also with the configuration t_2^5 , and for it, direct EPR and ODEPR studies have confirmed strong inward relaxation of one of its Se neighbors [6].) Again, as in the trapped Ga vacancy model above, the four nearest nitrogen neighbor hyperfine interactions would have to be weak enough to serve only to broaden the lines.

5. Discussion

The model in Fig. 2(a) requires the motion at room temperature of the N vacancy, for the model in Fig. 2(b), the Ga vacancy. Although possible, the onset of long-range motion for either almost simultaneously with that of the Ga interstitial would be a coincidence. On the other hand, the emergence of the isolated Ga vacancy ODEPR could follow naturally as its perturbing nearby the Ga interstitial migrates away. In addition, the model in Fig. 2(c) suggests a natural explanation for the 0.95 eV luminescence, which we have argued above must arise from an intrinsic defect, as directly resulting from the vacancy itself. This can be seen in Fig. 3. Here, we have taken advantage of the calculations of Neugebauer and Van de Walle [7], who estimated the triple acceptor level ($3-/2-$) of the vacancy to be at $\sim E_V + 1.1$ eV. With this, it is possible to identify, as shown, the Stokes-shifted and broadened 0.95 eV luminescence as arising from hole capture by the non-paramagnetic V_{Ga}^{3-} , which Jahn-Teller distorts in moving from $V_{\text{Ga}}^{3-}(t_2^6)$ to $V_{\text{Ga}}^{2-}(t_2^5)$.

Fig. 3. Model for the 0.95 eV PL and its various feeding and competing processes, assuming that L1 arises from the Ga vacancy.

Immediately after the low-temperature irradiation, each vacancy has a Ga interstitial frozen-in nearby, which supplies a highly effective feeding mechanism for the luminescence, as shown. It allows a Coulomb-attractive transfer of electrons to the interstitials, which are in the non-paramagnetic Ga_i^+ charge state. The electrons can then be transferred to the nearby $\text{V}_{\text{Ga}}^{2-}$, followed by hole capture, to produce the 0.95 eV PL. At the same time, electron transfer to those interstitials in the paramagnetic Ga_i^{2+} charge state provides the competing spin-dependent process leading to the L5 PLODMR.

Also shown is the less-efficient spin-dependent feeding process seen in the L1 ODEPR, which involves Coulomb-repulsive direct electron transfer to the paramagnetic $\text{V}_{\text{Ga}}^{2-}$, followed by hole capture, which becomes an important feeding process only after the Ga interstitial migrates away.

If this model turns out to be correct, then we would have observed both partners of the Frenkel pairs on the Ga sublattice, and we would have learned that the isolated Ga vacancy is stable to $\sim 600^\circ\text{C}$, at which temperature, it can migrate and disappear. At present, this is a working model. Determining whether it is correct or not will require more critical tests in future studies.

Electron paramagnetic resonance of GaN detected by recombination afterglow

U. Rogulis^{1,*}, S. Schweizer, J.-M. Spaeth

Department of Physics, University of Paderborn, Warburger Str. 100, 33095 Paderborn, Germany

Abstract

X-irradiation at 4.2 K of GaN produces a long lasting recombination afterglow (RL). This afterglow quenches in high magnetic fields, but it can be increased by applying microwave radiation (93 GHz) yielding resonance lines (RL-EPR) for appropriate magnetic fields. For a free standing GaN 'lift-off' layer, two overlapping RL-EPR lines with different half-widths and almost isotropic g -values were observed. The spin-lattice relaxation times were in the range of several minutes. The two resonances are detected in the red spectral range of the RL; one of these resonances is observed in the photoluminescence-detected EPR (PL-EPR) as well. A different RL-EPR spectrum was recorded in a Mg-doped GaN layer: The RL-EPR showed the line of the shallow donor. The features of the RL-EPR spectra of the two different GaN samples shows that RL in GaN involves additional electron and hole traps and thus provides additional information unattainable in PL-EPR. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; EPR; X-irradiation; Recombination afterglow

1. Introduction

GaN is a widely used material for blue laser diodes and other opto-electronic applications (see, for example, [1]). For AlN ceramics, doped with oxygen, magnetic resonance measurements yielded resonances which were attributed to the tunnelling recombination luminescence (RL) between well separated, oxygen related, donors and acceptors [2]. The method of recombination luminescence detected EPR (RL-EPR) was previously applied to the tunnelling RL in ionic crystals [3].

The motivation for the present work was to observe tunnelling recombination between the separated donor-acceptor pairs in GaN and to detect RL-EPR in comparison with that observed by the conventional photoluminescence detected EPR (PL-EPR) technique. We show that RL-EPR can provide additional information for the understanding of the recombination

processes in GaN and, in general, semiconductor materials.

2. Experimental

Two different GaN samples have been investigated: (i) a 250 μm thick free standing GaN 'lift-off' layer and (ii) Mg-doped MOVPE GaN layer on sapphire.

Luminescence-detected electron paramagnetic resonance spectra were recorded with a custom-built computer controlled spectrometer working at 93 GHz (W-band) with magnetic fields up to 4.5 T. All spectra were measured at 1.5 K using a cooled photomultiplier operating in the spectral range of 200–800 nm. In the case of PL-EPR measurements, the samples were excited in the UV spectral range with a deuterium lamp in combination with a 280 nm interference filter at 1.5 K. The PL-EPR was detected either in the integral luminescence for wavelengths larger than 380 nm or in different spectral ranges using edge filters.

The RL-EPR measurements, where the EPR is measured in the afterglow luminescence, were performed

*Corresponding author. Fax: +49-5251-603247.

either after excitation at 4.2 K with an X-ray tube (tungsten anode, 60 kV, 15 mA, irradiation time 20 min) or a deuterium lamp (280 nm in combination with an interference filter, irradiation time 1–2 h). The RL-EPR was detected either in the integral RL or in different spectral ranges using edge filters. In all the RL-EPR spectra, the magnetic field dependent background was subtracted.

3. Results

The UV-excited photoluminescence spectrum of the 250 μm thick free standing 'lift-off' GaN layer consists of bands between the yellow and blue spectral ranges (Fig. 1(a)). PL-EPR of a GaN layer, recorded at 1.5 K in W-band (Fig. 2(c)), shows two resonance lines with g -values of 2.005 and 1.95, respectively, in good agreement with results obtained by Bayerl [4].

After X-irradiation of the GaN 'lift-off' layer at 4.2 K, a recombination afterglow was observed for several hours. Fig. 1(b) shows a Gaussian approximation of the RL spectral dependence, measured with a set of edge filters in the integral RL. The RL occurs in the red spectral range with a band maximum at approximately 1.8 eV (690 nm).

The afterglow quenches in high magnetic fields (up to 3.6 T) at 1.5 K. It increases by a factor of 3 when applying a microwave radiation of 93 GHz at appropriate field values showing intense RL-EPR signals (Figs. 2(a) and (b)). RL-EPR is strongly influenced by very long spin-lattice relaxation times of several minutes. Therefore, we tried to measure the spectra with different integration times. Fig. 2 shows RL-EPR spectra of the GaN 'lift-off' layer recorded with a longer integration

Fig. 2. RL-EPR and PL-EPR spectra of GaN 'lift-off' layer, recorded at 1.5 K in W-band, in the integral luminescence: (a) RL-EPR spectra measured by increasing the magnetic field: curve (1) recorded with an integration time of 6 mT/min, the magnetic field and time dependent background are not subtracted, curve (2) measured as an RL difference by switching 'on' and 'off' the microwave power with a period of 8 s; (b) the same as (a) but measured by decreasing the magnetic field and (c) PL-EPR spectrum of the GaN 'lift-off' layer, recorded at 1.5 K in W-band. The PL was excited at 280 nm and measured with a 380 nm edge filter.

time in the direction of increasing (left to right) field (Fig. 2(a), curve 1) and decreasing (right to left) field (Fig. 2(b), curve 1). Tagged RL-EPR spectra are depicted as curves 2 in Figs. 2(a) and (b) and have been measured with 'on-off' modulation, that is, the difference between the RL intensity, when the microwave power is switched on and that when it is switched off with a period of 8 s. Under these conditions, we can resolve in the RL-EPR two overlapping resonance lines with different half-widths and g -values closer to $g = 2.00$.

We observed RL and RL-EPR spectra also in a Mg-doped GaN layer. The RL-EPR of the Mg-doped GaN layer shows one structureless resonance line of the shallow donor with $g = 1.96$ (not shown) at 1.5 K.

4. Discussion

The long lasting (for several hours) afterglow-RL in GaN samples after switching off the X-ray excitation or prolonged above-band-gap UV excitation is weak compared to the PL intensity. It can be quenched in high magnetic fields and partially restored by applying a microwave power at resonance magnetic fields.

Fig. 1. Spectra of GaN 'lift-off' layer, recorded at 4.2 K: (a) UV-excited PL spectrum and (b) a Gaussian approximation of the RL spectral dependence, measured with a set of edge filters in the integral RL at 4.2 K.

Therefore, the recombination process occurs between spatially well-separated paramagnetic donors and acceptors and is spin-forbidden in a high field, where they are almost parallel at low temperature unless the spins are flipped to be anti-parallel by magnetic dipole transitions in which state they can recombine into the singlet ground state and emit the recombination luminescence.

The effect of X-irradiation is probably due to recharge donors and acceptors which are in the tunnelling distances from each other to a paramagnetic state. The two resonances of the GaN 'lift-off' layer are seen in the red spectral range of the RL; one of them seems to be the resonance observed at $g = 2.005$ even in PL-EPR.

The RL-EPR spectrum, observed in the Mg-doped GaN layer, shows different RL-EPR lines compared to those observed in the GaN 'lift-off' layer. The RL-EPR of the Mg-doped GaN layer shows only one resonance line in contrast to the PL-EPR where resonance lines of Mg-related acceptors have also been observed [5].

These features of the RL-EPR spectra in different GaN samples show that RL can involve different electron and hole traps from those observed in PL-EPR. It makes additional traps visible, particularly those with very long spin-relaxation times, which are not seen in PL-EPR. Additional investigations are necessary to further analyse the mechanism of the recombination afterglow in GaN.

5. Conclusion

A tunnelling recombination afterglow and RL-EPR in GaN have been observed. The RL spectral shape

differs from the PL spectral shape. The RL-EPR may show a part of the PL-EPR lines as well as new resonance lines, particularly those with very long spin-lattice relaxation times. Probably, the effect of X-irradiation is to recharge donors and acceptors which are in a tunnelling distance from each other to paramagnetic charge states. RL-EPR can provide additional information on the recombination processes and luminescences in GaN and other semiconductor materials.

Abstract

The electronic noise properties of Si-doped AlN and Al_{0.3}Ga_{0.7}N are investigated. In AlN:Si, generation–recombination (g–r) noise is observed and shown to be linked to DX-centers. The potential energy barriers for capture into and emission from the DX[−] ground state are quantitatively determined from the noise measurements. In Al_{0.3}Ga_{0.7}N:Si, in addition to 1/*f* noise, we find two g–r noise processes. However, an unambiguous identification of their origin proves to be difficult. © 2001 Elsevier Science B.V. 1. Introduction

Recently, DX-like behavior of Si in AlN [1] and AlGaN alloys with high Al content [2] has been reported. Thus, in these materials, Si does not simply act as a shallow donor. Instead, it can form a complex, metastable deep defect. In AlGaAs alloys, such a behavior of Si and other dopants has been extensively studied [3]. It is of particular relevance for device applications, as it can seriously affect e.g. carrier densities. DX[−]-centers are formed because the donor atom can minimize its energy by undergoing a large lattice relaxation away from the substitutional position in combination with the capture of an extra electron. This is shown more quantitatively in the simplified configuration-coordinate diagram of Fig. 1. The lower parabola to the right corresponds to the lattice relaxed DX[−] ground state. The parabola above it symbolizes the thermodynamically metastable DX⁰ state, whereas the shallow substitutional donor level is depicted by the parabola to the left. The net energy difference between

the substitutional donor and the DX[−]-state (E_R in Fig. 1) governs the occupation of the two levels in thermal equilibrium. Thus, in AlN, the conductivity is not activated with ≈ 60 meV, as one would expect for a shallow effective mass donor in this material, but with $E_R = 345 \pm 3$ meV, a first experimental hint to the more complex DX-behavior of Si in AlN [1]. For the construction of a quantitative configuration coordinate diagram, especially for the determination of the potential energy barriers between DX[−] and DX⁰ states, electronic noise measurements have proven to be a valuable tool in AlGaAs alloys [4,5]. In this contribution, we show that from noise measurements the transition energies E_{up} and E_{down} (cf. Fig. 1) can be determined quantitatively for AlN:Si. We further compare the generation–recombination (g–r) noise observed in AlN:Si and in Al_{0.3}Ga_{0.7}N:Si.

2. Experimental

The samples investigated are epitaxial Al-face AlN and Al_{0.3}Ga_{0.7}N thin films grown by plasma-induced molecular beam epitaxy on (0001)-oriented sapphire substrates with a nominal Si doping density of $N_{Si} =$

Fig. 1. Simplified configuration coordinate diagram of the Si DX-center in AlN showing the levels relevant to the investigations presented here. A complete configuration coordinate diagram is given in Ref. [1].

$3 \times 10^{19} \text{ cm}^{-3}$ in the AlN and $N_{\text{Si}} = 4 \times 10^{17} \text{ cm}^{-3}$ in the $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}$ samples. For $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N} : \text{Si}$, a $\approx 10 \text{ nm}$ thick, nominally undoped AlN nucleation layer was grown before depositing the $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}$ layer. Alloyed-in Ti/Al/Pt/Au layers yielded good ohmic contacts. For the noise measurements, voltage fluctuations across the sample were amplified with a Stanford Research SR560 low-noise preamplifier and analyzed with a Stanford Research SR760 Fast-Fourier Transform spectrometer. A dry battery together with a series resistor of at least 20 times the sample resistance supplied the constant current necessary for the non-thermal noise measurements.

Typical non-thermal noise spectra from the AlN:Si and $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N} : \text{Si}$ samples are shown in Fig. 2. Due to the strong non-thermal noise, corrections for thermal noise and amplifier noise have not been necessary. As expected for resistance noise, the noise power density S_U scales quadratically with the voltage drop U across the sample. As especially the $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N} : \text{Si}$ samples show strong $1/f$ -noise in addition to g-r noise, it is more convenient to plot S_U/U^2 multiplied by frequency f . Then, the $1/f$ -noise appears as a constant background. In contrast, the Lorentzian characteristic of g-r noise

$$S_{U, \text{g-r}}(f) = \frac{S(f=0)}{1 + (2\pi f)^2 \tau^2}, \quad (1)$$

with the g-r noise power density $S(f=0)$ and the characteristic g-r time constant τ , becomes clearly discernible as a peak upon multiplication with f . The frequency where $f \times S_{U, \text{g-r}}/U^2$ peaks directly yields τ .

The second value characterizing g-r noise, $S(f=0)$, can be obtained using the identity $S(f=0) = 2S_{U, \text{g-r}}(f = (2\pi\tau)^{-1})$. This determination of $S(f=0)$ is not influenced by the low frequency $1/f$ -noise often observed. As evident from Fig. 2, both τ and $S(f=0)$ are strongly temperature dependent in AlN and $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}$.

3. Discussion

We now analyze the experimental results for AlN:Si in more detail. As discussed in Ref. [1], the DX-nature of Si in AlN is evident from the following experimental observations: At low temperatures and in the dark, the samples are observed to be highly resistive and no electron paramagnetic resonance (EPR) signal can be detected. Upon illumination with light of more than 1.5 eV, an increase of the conductivity by more than 7 orders of magnitude is observed. In addition, an EPR signal characteristic of shallow donors appears. Both the conductivity and the EPR signal persist after the light is switched off, and are quenched only at temperatures above 80 K. From persistent photoconductivity decay measurements, the transition energy (the potential barrier) impeding the transition from d^0 to DX^- (E_{up} in Fig. 1) can be estimated to $E_{\text{up}} \approx 100 \text{ meV}$. Because electronic noise, due e.g. to fluctuations of the number of mobile charge carriers, is governed by carrier dynamics, noise measurements can give valuable information about transition energies (E_{up} , E_{down} in Fig. 1). The most simple source of g-r noise is a two level system (TLS). In a very schematic picture, d^0 and DX^- can be considered as such a TLS, with charge carriers mobile only in d^0 . Machlup [6] showed that the g-r noise stemming from one single TLS is given by Eq. (1) with $S(f=0) = \pi^{-1} \tau_{\text{up}}^2 \tau_{\text{down}}^2 / (\tau_{\text{up}} + \tau_{\text{down}})^3$ and $\tau^{-1} = \tau_{\text{up}}^{-1} + \tau_{\text{down}}^{-1}$, where τ_{up} and τ_{down} are the carrier lifetimes in the two levels, respectively. Commonly, the electronic noise from DX-centers in AlGaAs alloys is interpreted following this idea [4]. The potential barriers E_{up} and E_{down} are assumed to govern the thermal activation of the lifetimes $\tau_{\text{up}} = \tau_{\text{up},0} \exp(E_{\text{up}}/kT)$ and $\tau_{\text{down}} = \tau_{\text{down},0} \exp(E_{\text{down}}/kT)$. $\tau_{\text{up},0}$ and $\tau_{\text{down},0}$ are considered to be independent of temperature, as the exponential factor by far dominates in the temperature range of interest here. Assuming $\tau_{\text{down}} \ll \tau_{\text{up}}$, the above expressions can be simplified to

$$S(f=0) \approx \pi^{-1} \tau_{\text{down}}^2 \tau_{\text{up}}^{-1}, \quad (2)$$

$$\tau^{-1} \approx \tau_{\text{down}}^{-1}. \quad (3)$$

Thus, because of Eq. (3), the thermal activation of τ directly yields $E_{\text{down}} = E_{\text{r}} = 391 \pm 8 \text{ meV}$. From Eq. (2), $E_{\text{up}} = 2E_{\text{down}} - E_{\text{Si}} = 48 \pm 27 \text{ meV}$. This value is in agreement with the one obtained from the relation evident from Fig. 1 $E_{\text{up}} = E_{\text{down}} - E_{\text{R}} = 46 \pm 9 \text{ meV}$,

Fig. 2. Typical non-thermal noise spectra of an AlN:Si sample (upper part) and an $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}:\text{Si}$ sample at different temperatures. To discriminate the g-r noise against a $1/f$ -noise background, the noise power density was multiplied by frequency.

and with the values estimated from persistent photo-conductivity measurements [2]. The assumption $\tau_{\text{down}} \ll \tau_{\text{up}}$ can be justified by considering the other limiting case: $\tau_{\text{down}} = \tau_{\text{up}} = \tau_0$. Then, $\tau \propto \tau_0$ and $S(f=0) \propto \tau_0$, in contrast to experiment.

We proceed to analyze the findings in $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}:\text{Si}$. The conductivity is activated with 20 ± 1 meV, in good agreement with the value of ≈ 22 meV predicted for an effective mass donor. An EPR signal typical for shallow donors ($g = 1.97$) in AlGaN alloys of this composition [7] is observed at low temperatures and in the dark. Upon illumination, the EPR signal intensity is persistently increased, as well as the conductivity, however only by about 20%. Above room temperature, the non-thermal noise is dominated by $1/f$ -noise. Below 300 K, a comparatively weak g-r noise component is observed (cf. Fig. 2). As in the case of AlN, both the characteristic g-r frequency τ as well as the g-r noise power density $S(f=0)$ are found to be thermally activated. We obtain $E_{\tau,1} = (309 \pm 10)$ meV and $E_{S_0,1} = (366 \pm 8)$ meV. For $T < 210$ K, a second g-r contribution appears, again thermally activated, with $E_{\tau,2} = (192 \pm 12)$ meV and $E_{S_0,2} = (180 \pm 10)$ meV.

Thus, in the $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}$ samples, there is no unambiguous evidence for the DX-behavior of Si. This is not surprising, as DX^- is the stable ground state for Si in AlGaN alloys only for an Al content higher than 60% according to the calculations of Boguslawski and Bernholc [8]. However, Kirtley et al. [4] have shown that the noise properties of AlGaAs:Si are still dominated by noise related to DX-centers even for alloy compositions where the DX-center is resonant with the conduction band. Fig. 3 gives a simplified sketch of the model proposed by Kirtley

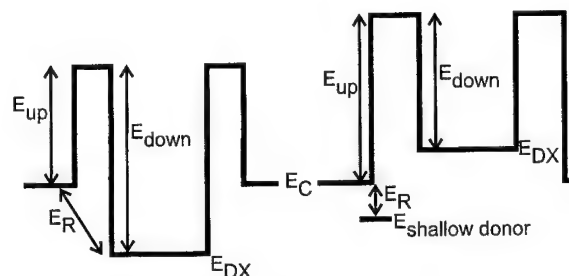

Fig. 3. Two-level system related to DX-centers for different alloy composition after Kirtley et al. [4]. The left part of the figure shows the energy levels for a deep DX-center, as it is encountered e.g. in AlN:Si. The right part suggests a possible situation for alloys in which the DX-center is not the energetically most favorable level at low temperatures (e.g. for DX resonant with the conduction band).

et al. In particular, the figure shows that while there is a sum rule connecting E_{up} , E_{down} and E_R for deep DX-centers (as e.g. in AlN:Si), there is no comparable relation between the activation of the conductivity and the characteristic g-r noise entities for DX-centers resonant with the conduction band. This makes an unambiguous identification of DX-centers as the noise source rather difficult. Thus, in the case of $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}:\text{Si}$, an attribution of the g-r noise observed to DX-centers is at best speculative. The data available so far, especially the observation of two separate g-r components, could just as well be explained in terms of conventional deep defects. Obviously, only further investigations with samples of varying alloy composition and Si doping density could help clarify the possible existence and

importance of DX-centers for low Al contents in AlGaN alloys. On the other hand it is important to note that in $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N} : \text{Si}$, g-r noise is observed, while in GaN only $1/f$ -noise is typically reported.

4. Conclusions

In summary, we have observed DX-behavior of Si in AlN. Noise spectroscopy has proven to be a valuable tool to quantitatively determine transition energies between DX^- and d^0 . In $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N} : \text{Si}$, however, a weak persistent photoconductivity and persistent EPR signal as well as two independent g-r noise contributions are observed at low temperatures indicating the possible DX-behavior of Si in these alloys too.

Abstract

The Mu^+ defect centers in AlN and GaN are studied using muon nuclear-quadrupole level-crossing resonance (QLCR) and zero-field muon spin depolarization measurements. The dominant Mu^+ center is highly mobile, but QLCR spectra identify a second static Mu^+ state at $\text{AB}_{\parallel}(\text{N})$ sites in both nitrides. This state becomes mobile above 800 K in AlN, but converts to a Mu^- above 200 K in GaN. Zero-field data characterize local fields and motional properties for this state in AlN. Above 1100 K the mobile Mu^+ in AlN shows strong interactions and traps at another defect. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The group-III nitrides, especially their alloys, are important materials for short wavelength optical devices. Hydrogen interacts with dopants and other defects to modify the electrical activity of the nitrides, see [1], as in other semiconductors. This activity makes hydrogen an important impurity, but also makes *isolated* hydrogen defects difficult to study. Muonium (Mu) is effectively a very light, short-lived pseudo-isotope of hydrogen formed by implanting positive muons. Muonium forms states very similar to those expected for hydrogen and, because of its short lifetime ($\tau = 2.197 \mu\text{s}$), Mu primarily occurs as an isolated impurity. Much of the experimental data associated with isolated H defects in many semiconductors comes from investigations of the muonium analog.

The wurtzite structure of GaN or AlN has two inequivalent bonds, thus there are two different bond-center (BC) sites, and two anti-bonding (AB) sites for each atom. AB_{\parallel} sites lie in a confined region formed by the stacking sequence and have Mu-Ga(Al) or Mu-N directions parallel to \mathbf{c} . Each atom has three AB_{\perp} sites, directed at $\sim 70^\circ$ to \mathbf{c} into unblocked channels providing a path for diffusion, or for local motion among three closely spaced sites. Based on theoretical studies [2–5] one can expect either BC or $\text{AB}(\text{N})$ sites for Mu^+ ; BC, $\text{AB}(\text{III})$, or more likely a symmetric central channel site for Mu^0 ; and either $\text{AB}(\text{III})$ or a more centralized channel location for Mu^- .

We previously investigated the sites and dynamics of Mu^- in n-type GaN [6–8], finding that Mu^- resides at the two Ga antibonding locations, and that the mobile Mu^- channel state completely dominates at high temperatures. In the present contribution, we report on the locations and dynamics found for Mu^+ centers in GaN and AlN. One of these states is quite mobile in both nitrides and represents the majority of charged

*Corresponding author. Tel.: +1-806-742-3697; fax: +1-806-742-1182.

E-mail address: xbrll@ttacs.ttu.edu (R.L. Lichti).

centers in higher quality AlN. This state is associated with a slowly relaxing component in zero-field muon spin depolarization measurements, where static centers have a distinctive signature characteristic of nuclear dipolar fields at their respective locations. Assignment of the weakly relaxing component to a mobile Mu^+ in the wurtzite channels is based on theoretical expectations and a process of elimination in GaN, where all other anticipated isolated states are separately identified. The lone remaining site, $\text{AB}_{\perp}(\text{N})$, gives a low energy state for Mu^+ [2,4] and should be relatively mobile. Unfortunately, extracting site details or accurate dynamics for this state is not possible, so the information remains qualitative for the primary Mu^+ centers. In the following we describe signals assigned to the less mobile (theoretically metastable) Mu^+ centers and summarize site assignments and dynamics.

2. Results and discussion

QLCR spectra are due to resonant cross relaxation between muon Zeeman levels and quadrupolar levels of a neighboring nucleus. These transitions are driven by dipole–dipole interactions between the muon and its neighbor which mix the muon spin states thereby reducing the muon polarization. Resonances occur for magnetic fields at which energies of non-interacting states of the combined muon and nuclear spins would cross. The locations and strengths of QLCR resonances carry information on the dipolar and nuclear quadrupolar interactions induced by the muon, thus contain details of the local defect structure. If the muon-induced electric field gradient (EFG) dominates the intrinsic one, as appears to be the case, its principle axis lies along the muon–nucleus bond. Each host atom has a quadrupole moment: $I = 3/2$ for both ^{69}Ga and ^{71}Ga ; $I = 5/2$ for ^{27}Al ; and $I = 1$ for ^{14}N . The two isotopes give a definitive identification of any Ga resonances. Strong Ga resonances imply Ga nearest neighbors and are assigned to Mu^- states or to Mu^+ in a BC site.

Fig. 1a shows a QLCR spectrum for GaN having both Mu^+ and Mu^- features. The Ga related lines are from the two $\text{AB}(\text{Ga})$ sites for Mu^- as previously reported [6,7]. To extract the N related line which overlaps the lower-field ^{71}Ga resonances, at each temperature the higher field ^{69}Ga lines were fit with all parameters free and the ^{71}Ga lines were then scaled according to theoretical expectations. The remaining feature just below 10 mT is a single line and results in smooth temperature dependences for the related fit parameters, giving considerable confidence in the spectral separation. No other lines are present below 150 K with comparable intensity, thus this line was assigned to an N atom with its EFG tensor aligned along the applied field direction, i.e. the c -axis.

The most reasonable option for a static isolated Mu center to associate with this N-related QLCR signal is a Mu^+ at the $\text{AB}_{\parallel}(\text{N})$ site. A BC_{\parallel} location could work except that no Ga resonances with a similar temperature dependence were observed. Any other muon position close enough to a nitrogen to give the correct intensity would result in an EFG tensor oriented well away from the c -axis. This state can therefore reasonably be assigned to a Mu^+ trapped in the confined cage region of the wurtzite structure. Since the signal is strongest at the lowest temperatures, it is most likely formed during implantation, when a bare muon enters the cage at the end of its thermalization path.

Fig. 2 displays the temperature dependence of the QLCR amplitudes for Mu^+ at $\text{AB}_{\parallel}(\text{N})$ and Mu^- at $\text{AB}_{\parallel}(\text{Ga})$, showing a transformation from Mu^+ to Mu^- near 200 K. Similarly, combined QLCR and depolarization data imply partial conversion of the mobile Mu^+ to Mu^- at $\text{AB}_{\perp}(\text{Ga})$ in this region and complete transformation above 600 K [8].

Results shown here suggest multiple transitions in the 200 K region, as do the depolarization data [6,8]. Obviously, a change from Mu^+ to Mu^- must go through a neutral, although perhaps unstable, Mu^0 state. Fits to the decrease in $\text{AB}_{\parallel}(\text{N})$ amplitude as two activated processes give $E_1 = 0.16(\pm 0.03)$ eV and $E_2 = 0.26(\pm 0.05)$ eV for transitions out of Mu^+ . A two step decrease in the mobile Mu^+ zero-field component for heavily doped n-type GaN is also consistent with these values [6].

For AlN, a strong resonance is seen at 4.2 mT in Fig. 1b with a weaker line centered near 6 mT. The strong resonance has the same characteristics as the N-related line in GaN, and is assigned to the same state, a Mu^+ at $\text{AB}_{\parallel}(\text{N})$. The second resonance has no visible partner, although a similar line at lower field could be obscured by the larger features. The width suggests slow dynamics for this second state and its temperature dependence does not match the dominant one. At present we cannot assign a site or symmetry to the weaker feature; although, a Mu^+ state at $\text{AB}_{\perp}(\text{N})$ would give two lines, the higher field one roughly in this position if the EFGs are similar for the two $\text{AB}(\text{N})$ locations, as seen (Fig. 1a) for Mu^- at $\text{AB}(\text{Ga})$ sites in GaN.

Motional dynamics could be extracted from the QLCR data; however, a more sensitive technique is zero-field depolarization, for details see [9]. For a static state in a system with numerous nearby nuclear moments, the depolarization follows a Gaussian Kubo–Toyabe (KT) function. In our analysis of AlN zero-field data, a KT component represents Mu^+ at $\text{AB}_{\parallel}(\text{N})$ and a slowly relaxing component is assigned to the mobile Mu^+ channel state. The primary parameter for a static state is the KT linewidth, Δ_{KT} , which characterizes the mean strength of randomly oriented

Fig. 1. Typical QLCR spectra; specifically shown for Mu^+ and Mu^- in partially compensated GaN (a) and Mu^+ in bulk polycrystalline AlN (b).

nuclear dipolar fields at equivalent sites. We obtain $\Delta_{\text{KT}} = 326(\pm 3)$ kHz for Mu^+ at $\text{AB}_{\parallel}(\text{N})$. When the Mu^+ state is mobile, the shape of this function changes with the hop rate, eventually becoming nearly exponential for rapid motion. Hop rates for two AlN samples shown in Fig. 3 were obtained from zero-field data analyzed with Δ_{KT} fixed to the static value. The activation energies found from these data sets are $1.04(\pm 0.07)$ eV and $0.96(\pm 0.06)$ eV. In our model of these states, this 1.0 eV barrier represents the energy required to escape from the cage into the channels, which would likely occur through BC_{\perp} sites with Mu^+ remaining attached to a single N atom.

The slowly relaxing component was treated as a Gaussian in the zero-field fits. The fraction of muons forming the low- T mobile state increased with visual quality of the samples from lowest (25%) in bulk polycrystalline AlN to highest (70%) in sublimation

grown single-crystal thick films, with a corresponding decrease in static Mu^+ (40% to 20%) and atomic-like Mu^0 (35% to 10%) fractions. Below 900 K the slow relaxation rate was nearly constant at $\sigma = 21(\pm 2)$ kHz in several samples. General characteristics suggest tunneling motion for this Mu^+ state; a very rough estimate of the hop rate gives $\nu_0 \approx 10$ MHz. For the largest cross-section film (deposited by CVD), the relaxation rate increased slowly above 950 K to 38 kHz at 1140 K implying stronger interactions with nuclear moments. At the highest temperature some fraction of the mobile Mu^+ species becomes trapped at another defect, yielding a static component with $\Delta_{\text{KT}} \geq 400$ kHz, significantly larger than for the static Mu^+ below 750 K.

In conclusion, we have investigated the sites and dynamics of Mu^+ defect centers in GaN and AlN. We find a QLCR signature of a static Mu^+ located at

Fig. 2. Temperature dependent QLCR amplitudes showing a conversion from Mu^+ to Mu^- for AB_{II} cage sites in GaN.

Fig. 3. Hop rates associated with the $\text{AB}_{\text{II}}(\text{N})$ site for Mu^+ in two AlN samples. The barriers for motion are about 1.0 eV.

$\text{AB}_{\text{II}}(\text{N})$ sites in both nitrides. This state converts to Mu^- in a complicated set of transitions near 200 K in (n-type) GaN and is extremely stable in AlN, where it shows

motion or site change dynamics only above 750 K with a characteristic energy very close to 1.0 eV. We infer the presence of a mobile Mu^- state in both nitrides from a slowly relaxing diamagnetic Mu component in zero-field depolarization measurements. In GaN, most of the mobile Mu^+ species also converts to a by-then-mobile Mu^- state at elevated temperatures. The mobile Mu^- state has nearly constant dynamics up to 900 K in AlN, but at higher temperatures shows increasing interactions and traps at an unknown impurity by 1150 K. Since the investigated AlN samples all have significant oxygen content, we suggest an oxygen related trap site, but have no direct evidence of the specific trapped state.

Abstract

We have applied positron annihilation spectroscopy to show that 2 MeV electron irradiation at 300 K creates Ga vacancies in GaN with an introduction rate of 1 cm^{-1} . The Ga vacancies recover in long-range migration processes at 500–600 K with an estimated migration energy of 1.5(2) eV. Since the native Ga vacancies in as-grown GaN are stable up to 1300–1500 K, we conclude that they are complexes with oxygen impurities. The estimated binding energy of 2.2(4) eV of such complexes is in good agreement with the results of theoretical calculations. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Ga vacancy; Irradiation; Positron annihilation

1. Introduction

Gallium nitride and its alloys form a class of important semiconductor materials for applications in optoelectronics at blue wavelength and electronic devices operating at high temperature and high voltage. Ga vacancies have been observed as important native defects in n-type GaN by positron annihilation spectroscopy [1,2]. However, the experiments so far have given only limited information on their formation mechanism during the crystal growth. Electron irradiation is a very valuable technique to introduce basic point defects in a controlled way. The annealing treatments of the irradiated material yield important information on the thermal stability of isolated intrinsic point defects. Such knowledge is helpful for understanding how native defects are formed during the growth.

Positrons get trapped at neutral and negative vacancies because of the missing positive charge of the ion

cores. The reduced electron density at vacancies increases the positron lifetime. In this paper, we apply positron annihilation spectroscopy to identify the Ga vacancies formed in 2 MeV electron irradiation of GaN bulk crystals. We study the annealing behavior of Ga vacancies and compare the thermal stabilities of native and irradiation-induced V_{Ga} . We further extend our earlier work [3] to discuss in greater detail the temperature dependence of positron lifetime in irradiated GaN.

2. Experimental details

The bulk GaN crystals were grown at a nitrogen pressure of 1.5 GPa and temperature of 1500°C [4]. Semi-insulating Mg-doped samples were chosen for the experiment, since these are free of native Ga vacancies as shown earlier [5]. The Mg and O concentrations of the samples were $[\text{O}] \approx [\text{Mg}] \approx 10^{20} \text{ cm}^{-3}$ according to secondary ion mass spectrometry [5]. The samples were irradiated with 2 MeV electrons at 300 K to two fluences of $\Phi = 3 \times 10^{17}$ and $1 \times 10^{18} \text{ cm}^{-2}$. The positron lifetime experiments were performed using conventional instrumentation with the time resolution 230 ps [2].

Fig. 1. Average positron lifetime as a function of annealing temperature T_{ann} in two GaN samples irradiated to fluences Φ . The measurement temperature was $T_{\text{meas}} = 300 \text{ K}$. The dashed line shows the level of the average positron lifetime in as-grown samples before irradiation [3].

To study simultaneously, the recovery of irradiation-induced defects and the temperature dependence of the positron lifetime spectrum, we annealed the samples in 10^{-3} mbar vacuum at temperatures T_{ann} and measured thereafter positron lifetimes as a function of measurement temperature T_{meas} from 80 K up to $T_{\text{ann}} - 50 \text{ K}$. The measurement time of positron lifetime spectrum (typically 3–4 h) is longer than the annealing time (30 min), which was observed to induce small recovery effects when measurements were performed close to T_{ann} . However, the final annealing curve (Fig. 1) was constructed of systematical data measured immediately after cooling the sample to room temperature from the annealing temperature T_{ann} .

3. Positron lifetime results

In unirradiated Mg-doped GaN samples only a single exponential decay component with a lifetime $\tau = 160 \text{ ps}$ is observed. As explained earlier [5], heavily Mg-doped GaN is free of Ga vacancies trapping positrons, and the lifetime $\tau = \tau_B = 160 \text{ ps}$ corresponds to positrons annihilating as delocalized particles in the defect-free GaN lattice. The 2 MeV electron irradiations with fluences $\Phi = 3 \times 10^{17}$ and $1 \times 10^{18} \text{ cm}^{-2}$, increase the average positron lifetime by 2 and 5 ps, respectively. This increase is a direct evidence of vacancy defects introduced in the samples in the electron irradiation. Fig. 1 shows the average positron lifetime τ_{av} at $T_{\text{meas}} = 300 \text{ K}$ as a function of the annealing temperature T_{ann} . Almost

Fig. 2. Average positron lifetime as a function of measurement temperature T_{meas} . The temperature dependence was measured after annealing the sample at different temperatures T_{ann} . The dashed line shows the level of the average positron lifetime in as-grown samples before irradiation.

no recovery of τ_{av} is observed up to $T_{\text{ann}} = 450 \text{ K}$. At 500–600 K, the average lifetime decreases and finally coincides with the positron lifetime of about $\tau_B = 160 \text{ ps}$ in defect-free GaN. This indicates the recovery of the irradiation-induced vacancy defect at 500–600 K.

A careful experiment with high statistical accuracy [3] shows that the lifetime spectrum in irradiated GaN has two exponential components. The longer lifetime component, $\tau_2 = 235 \pm 5 \text{ ps}$ corresponds to positrons trapped at the irradiation-induced vacancy defect. This lifetime is the same as we have earlier found for native defects formed during the growth of n-type GaN [1,5]. The native vacancy is thus the same defect as that introduced by electron irradiation at 300 K, i.e. the open volume in both of them corresponds to a single missing atom from the lattice site. As explained earlier in detail [6], the defect with the lifetime $\tau_V = \tau_2 = 235 \pm 5 \text{ ps}$ can be identified as the Ga vacancy or a complex involving V_{Ga} .

The temperature dependencies $\tau_{\text{av}}(T_{\text{meas}})$ of the average positron lifetime after various annealing treatments are plotted in Fig. 2. After annealings at $T_{\text{ann}} = 300$ –450 K, the average lifetime decreases at low temperatures, indicating that fewer positrons

annihilate while trapped at vacancies. The same behavior has been observed earlier in as-grown Mg-doped GaN [5] as well as in many other semiconductors [7]. The decrease of τ_{av} is due to negative Mg_{Ga}^- ions capturing positrons at hydrogenic states at low temperatures [5]. This trapping prevents positrons from getting into the vacancy defects, thus decreasing the average lifetime towards the bulk value τ_B at low temperatures. After annealing at $T_{ann}=600$ K the average positron lifetime increases only slightly with temperature (Fig. 2). The slope of τ_{av} vs. T is similar to that found earlier in GaN(Mg) samples without vacancies and can be associated with the thermal expansion of the lattice. This confirms further that vacancies introduced in the electron irradiation recover after annealing at 500–600 K.

Fig. 1 shows that the concentration of Ga vacancies in 2 MeV electron irradiation increases with the fluence. The quantitative analysis of the V_{Ga} concentrations and the introduction rate can be done with the positron trapping model [7]. We proceed as earlier [5] and take into account both vacancies and negative ions as positron traps. When the concentration of negative ions is fixed to the Mg concentration $c_{ion}=10^{20} \text{ cm}^{-3}$ determined in these crystals using secondary-ion mass spectrometry [5], we can deduce the Ga vacancy concentrations from the measured average positron lifetime. Notice that the possible irradiation-induced negative ions do not play any role in this analysis because the concentration of negative Mg_{Ga}^- in the samples is 10–100 times larger than that of any defect formed in the irradiation.

Fig. 3 shows that the concentration of Ga vacancies increases linearly with the electron irradiation fluence in the range $\Phi = (0-10) \times 10^{17} \text{ cm}^{-2}$. The introduction rate is roughly $\Sigma_V = c_V/\Phi = 1 \text{ cm}^{-1}$. This is a typical value for primary defects formed in the irradiation. Furthermore, the same introduction rate has been determined for Frenkel pairs in the nitrogen sublattice using 0.7–1 MeV irradiation [8]. For 2 MeV electrons, the electrical experiments show a total acceptor introduction rate of $1-2 \text{ cm}^{-1}$ [9]. This value is close to that determined here for Ga vacancies, but other acceptors, such as the N interstitials [8], most likely also contribute in the electrical experiments.

Chow et al. [10] have recently applied optical detection of electron paramagnetic resonance (ODEPR) to observe the interstitial Ga and related defects in irradiated GaN. According to their results, the Ga interstitial is mobile at room temperature and subsequently gets trapped, perhaps by oxygen impurities in the sample. It is clear that this trapped Ga interstitial must have left a Ga vacancy behind in the irradiation. In perfect agreement with the results of Chow et al. [10] we thus detect the irradiation-induced Ga vacancy after similar 2 MeV irradiation at 300 K.

Fig. 3. The concentration of Ga vacancies as a function of 2 MeV electron irradiation fluence at 300 K. The solid line corresponds to the introduction rate of $\Sigma_V = 1 \text{ cm}^{-1}$ [3].

Fig. 1 shows that the Ga vacancies recover in 30 min isochronal heat treatments at 500–600 K. The defects associated with trapped Ga interstitials are stable at 500–600 K and anneal at clearly higher temperatures of 700–900 K according to Bozdog et al. [11,12]. This suggests that Ga vacancies recover by becoming mobile defects at 500–600 K. Assuming that the vacancy takes roughly 10^3-10^5 jumps with an attempt frequency 10^{13} s^{-1} in the 30 min annealing time, we can convert the recovery temperature of 600 K to an activation energy of 1.5(2) eV. This value can be taken as an estimate for the migration energy of Ga vacancies in GaN.

The native Ga vacancies observed in as-grown n-type GaN are stable up to much higher temperatures than 600 K, where the irradiation-induced Ga vacancies recover. This points out directly that the Ga vacancies formed during the growth are not isolated but belong to stable defect complexes, most likely with O impurities as suggested earlier [13]. At growth temperatures (typically > 1300 K) negatively charged Ga vacancies are mobile and migrate in the lattice until they are trapped at positive oxygen donors. In fact, our preliminary results show that native Ga vacancy complexes recover in heat treatments at 1300–1500 K in samples grown by metal-organic chemical vapor deposition at about 1300 K. The recovery temperature of 1400 K corresponds to an activation energy of 3.7(2) eV, which can be interpreted as the sum $E_M + E_B$ of the migration energy of V_{Ga} and the binding energy of the $V_{Ga}-O_N$ complex. Taking the migration energy $E_M = 1.5(2) \text{ eV}$ determined above, we get a binding energy of $E_B = 2.2(4) \text{ eV}$ for the $V_{Ga}-O_N$ pair. This value is in excellent

agreement with the theoretical estimates of 1.8–2.1 eV [14,15].

4. Conclusions

We have identified Ga vacancies formed with the introduction rate of 1 cm^{-1} in 2 MeV electron-irradiation of GaN bulk crystals at 300 K. The Ga vacancies recover in heat treatments at 500–600 K. According to previous ODEPR experiments [10–12] Ga interstitials are trapped by other defects at this temperature range and anneal only above 700 K. We thus conclude that Ga vacancies become mobile defects at 500–600 K and recover in long-range migration processes, with an estimated migration energy of 1.5(2) eV. These results indicate that the native Ga vacancies formed during the crystal growth are associated with defect complexes, probably with the oxygen donors. We estimate a binding energy of 2.2(4) eV for these complexes, indicating that they are stable at the elevated growth temperature of GaN. Our results show further that Mg impurities are negatively charged in highly resistive Mg-doped GaN bulk crystals.

Abstract

Epitaxial GaN thin films were grown by low-energy nitrogen ion beam assisted deposition of gallium on *c*-plane sapphire. By applying X-ray diffraction and transmission electron microscopy, the influence of the ion irradiation induced defects on the formation of the undesired cubic GaN polytype in the hexagonal films is investigated. The results show that in all films containing the cubic polytype it appears in twinned form. An increase of the ion energy as well as the ratio of nitrogen ion flux and gallium atom flux (*I/A*-ratio) leads to an increase in the amount of cubic polytype in the films. The observations are discussed considering the ion beam induced defect creation. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Ion beam assisted deposition; GaN polytypes; XRD pole figures; Ion beam induced defects

1. Introduction

As the binding energy difference between the Ga–N bond in the stable hexagonal (wurtzitic) and metastable cubic (zincblende) polytype of GaN is only about 20 meV [1], the probability of stacking faults is high, i.e. zincblende GaN (*z*-GaN, *c*-GaN) often found in films intended to be purely wurtzitic GaN (*w*-GaN, *h*-GaN) and vice versa [2,3]. The necessary deposition conditions to obtain pure hexagonal films are published for GaN films grown by molecular beam epitaxy (MBE) or metal-organic vapour phase epitaxy (MOVPE) to be grown in the nitrogen-rich regime and at high temperatures [3,4]. The deposition of GaN films using energetic nitrogen ions is expected to influence these necessary growth conditions due to the large energy input into the surface region and the ion beam induced defect creation. The displacement energy of GaN, i.e. the energy that must be at least transferred in an elastic atomic collision in order to create a permanent point defect in GaN, is about 24 eV [5].

In this paper, the ion energy was chosen that high defects are created by ion impingement, but only within the first few nanometres of the growing GaN film. The appearance of the cubic polytype and the effect of the ion beam parameters on the cubic fraction of GaN films grown on *c*-plane sapphire, that is usually used for growth of *h*-GaN, is investigated.

2. Experimental

The GaN thin films were grown in a high vacuum chamber with a base pressure of 5×10^{-6} Pa by evaporating gallium with an effusion cell onto a *c*-plane sapphire substrate and simultaneously irradiating the growing film with hyperthermal nitrogen ions delivered by a Kaufman-type ion source. The gallium atom flux and the nitrogen ion flux was measured by a quartz crystal and a Faraday cup array, respectively. The process temperature, monitored by thermocouples, was held constant at 750°C. The arrival ratio of nitrogen ions to gallium atoms (*I/A*-ratio) was varied between 0.35 and 1.0 by alteration of the gallium flux at a constant nitrogen ion current density of 20 $\mu\text{A}/\text{cm}^2$. The ion energy *E* was

*Corresponding author. Tel.: +49-341-235-2682; fax: +49-341-235-2595.

E-mail address: jwgerlach@uni-leipzig.de (J.W. Gerlach).

in the range of 50–150 eV. The total film thickness of GaN was about 300 nm.

X-ray diffraction (XRD) measurements were performed with Cu-K α radiation using a four-circle goniometre with Eulerian cradle and a secondary graphite monochromator. To measure a pole figure the sample was rotated (azimuthal angle φ) at increasing sample tilts (polar angle χ) in a fixed θ -2 θ -geometry with a step width of 1° in φ and χ . The diffracted intensity distribution is illustrated in stereographic projection.

Cross-section TEM micrographs were obtained by an electron microscope with an acceleration voltage of 300 kV and an electronic image acquisition system.

3. Results and discussion

To distinguish between the *h*-GaN and *c*-GaN, texture measurements were performed. In Fig. 1 the hexagonal {10 $\bar{1}$ 1} and the cubic {111} XRD pole figure of a typical GaN film containing both polytypes prepared by IBAD is shown. From the fact that distinct, separated and narrow pole density maxima are visible it can be concluded that the film is of high crystalline order. Further, the number of pole density maxima in the cubic pole figure reveals that the cubic polytype appears in a two-fold form in the film. If there were only one cubic crystallite orientation in the thin film, arranged by stacking (111) planes in the order ABCABCA..., then only three-pole density maxima at a polar angle of 70.5° with an equal azimuthal distance of 120° would be present in the pole figure. The existence of a second set of three-pole density maxima, rotated against the first set by 180°, proves the existence of the cubic rotational twin, arranged by stacking (111) planes in the order ACBACBA..., in the film. Consequently, the two cubic twins have the epitaxial relationship

$$c\text{-GaN}(111)\parallel c\text{-GaN}(111),$$

and

$$c\text{-GaN}[\bar{1}\bar{1}0]\parallel c\text{-GaN}[\bar{1}\bar{1}0].$$

In all samples grown for this study it was found that the ratio of diffracted intensity originating from the two twins is about unity. This is understandable, as the stacking orders given above have equal probabilities. The epitaxial relationship between hexagonal and cubic polytypes as derived from the pole figures is

$$h\text{-GaN}(0001)\parallel c\text{-GaN}(111),$$

and

$$h\text{-GaN}[2\bar{1}\bar{1}0]\parallel c\text{-GaN}[\bar{1}\bar{1}0] \text{ or } c\text{-GaN}[\bar{1}\bar{1}0].$$

Fig. 1. Hexagonal {10 $\bar{1}$ 1} and cubic {111} XRD pole figures of a thin GaN film containing a mixture of both polytypes. The dotted circles indicate the φ -scans that were measured to obtain the phase index.

These relationships arise from the [0001] growth direction of the hexagonal GaN. Stacking faults in the hexagonal stacking sequence ABABA... can lead to the cubic polytype, as the (0001) plane of *h*-GaN and the (111)-plane of *c*-GaN are almost identical.

Together with the known epitaxial relationship between hexagonal GaN and sapphire [6] the epitaxial relationships between the cubic twins and sapphire are given by

$$\text{Al}_2\text{O}_3(0001)\parallel c\text{-GaN}(111),$$

and

$$\text{Al}_2\text{O}_3[\bar{1}\bar{1}00]\parallel c\text{-GaN}[\bar{1}\bar{1}0] \text{ or } c\text{-GaN}[\bar{1}\bar{1}0].$$

A semi-quantitative measure of the fraction of the cubic phase in the GaN film can be obtained by measuring φ -scans as indicated by the dotted circles in the pole figures in Fig. 1 and calculating the phase index (PIX), defined by

$$\text{PIX} = \frac{\int_0^{2\pi} I_{(111)} d\varphi}{\int_0^{2\pi} I_{(111)} d\varphi + \int_0^{2\pi} I_{(10\bar{1}1)} d\varphi} \quad (1)$$

with $I_{(hk.l)}$ being the diffracted intensity. Obviously, the PIX does not give the real concentration of the *c*-GaN in the sample. For this purpose pure and mixed hexagonal and cubic GaN samples with known film thickness and with comparable crystalline quality would be necessary for obtaining calibration factors. However, in order to compare films with different cubic content the PIX is a simple and reliable measure.

As can be derived from Fig. 2a and b, showing the PIX as a function of the ion beam parameters I/A and E , the variation of both parameters influences the cubic amount in the GaN films. The first observation is the increase of the cubic amount with increasing I/A -ratio, i.e. increasing nitrogen to gallium arrival ratio. This is contrary to the results known from MBE and MOVPE, where the cubic amount drops with increasing nitrogen-rich growth and rises with increasing gallium-rich

Fig. 2. Phase index PIX, i.e. cubic intensity fraction as a function of I/A -ratio (a) and ion energy (b).

Fig. 3. TEM micrographs (zone axis: sapphire $[1\bar{1}000]$) of a GaN film deposited with $I/A = 0.7$ and $E = 50$ eV: bright field image (a) with corresponding diffraction pattern (b), dark field images excited with $(1\bar{1}1)$ of first cubic twin (c) and second cubic twin (e) with corresponding selected area diffraction patterns (d, f). The white arrows indicate the spots used for the dark field images.

growth [3,4]. A proof for this unfamiliar behaviour of the cubic phase content in GaN films grown by IBAD is that the density of gallium droplets observed on films prepared with I/A -ratios of 0.35 to 0.7 diminishes with increasing I/A -ratio and vanishes for $I/A = 1.0$ (not shown here). This marks the transition from gallium-rich to nitrogen-rich growth which would lead to a decrease in the cubic amount of MBE and MOVPE GaN films in contrast to the results obtained for IBAD GaN films. The second observation is the trend of the cubic fraction to increase with higher ion energies.

As XRD measurements deliver integral information due to the high penetration depth of X-rays, electron microscopical investigations were conducted to obtain

local information on the nature of the cubic polytype detected by XRD. Because both extended cubic domains as well as a high density of stacking faults could result in the obtained diffracted intensity ratios. The TEM cross-section bright-field micrograph of a GaN film deposited with $I/A = 0.7$ and $E = 50$ eV in Fig. 3a shows two regions divided by a v-shaped insertion at the film surface. The side walls of this insertion and the film surface build an angle of about 55°. This matches the angle between the (111) and (001) planes in cubic crystals and therefore it can be concluded that the insertion walls are (001) facets of coalesced cubic domains. The corresponding overall diffraction pattern (Fig. 3b) shows a variety of relatively sharp diffraction

spots. By choosing only one of these spots (marked with a white arrow) and creating a dark-field image with this single spot, in fact two domains (see bright image parts) can be distinguished in Fig. 3c and e which extend over the whole film thickness. The selected area diffraction patterns of the left and the right domain (Fig. 3d and f) are characteristic of cubic systems and can be assigned to two different cubic twins as already observed by XRD. It has to be noted that this selected sample region does not contain any hexagonal GaN at all, but that hexagonal GaN was found in other regions of the film.

The results presented above allow the following conclusions:

(i) The increase of the cubic fraction with both increase of I/A and E is definitely correlated with the ion beam irradiation during growth. The increase in the two parameters results in a higher defect production and, due to the larger penetration depth of nitrogen ions with higher ion energy, in a broader region where defects are created. However, it still has to be kept in mind that the mean projected range of nitrogen ions in GaN as calculated by the Monte-Carlo code TRIM [7] is only two to three monolayers for the chosen ion energies and the created defects are not annealed out at the deposition temperature (see Ref. [8]).

(ii) The formation of the cubic phase during ion beam assisted growth of GaN is a nucleation phenomenon at the substrate surface, as the domains extend over the whole film thickness and no growth of hexagonal GaN or the complementary cubic twin occurred in these domains.

(iii) The ion beam irradiation during deposition stabilizes the growth of the metastable cubic polytype. However, the mechanism of stabilization of the cubic phase due to ion beam induced defects in the surface region, that was also assumed by Lee et al. [9], is not clear up to now. Furthermore, it was found that the compressive stress in films of the present study was up to 600 MPa [10]. Therefore, an additional influence of mechanical stress on the polytype stabilization may be taken into account.

4. Summary

The influence of the ion irradiation during low-energy nitrogen ion beam assisted deposition of gallium on *c*-plane sapphire substrates was investigated with respect to the formation of the cubic polytype. The results show that *c*-GaN appears in large twinned domains and that an increase of the nitrogen ion to gallium atom flux ratio, as well as an increase of the ion energy favours the formation and stabilization of *c*-GaN.

Abstract

Optically detected electron paramagnetic resonance (ODEPR) measurements in the yellow luminescence (YL) under pressures up to 7 GPa have been performed. A non-magnetic diamond anvil cell was designed, into which microwaves in the 4 mm band (72 GHz) could be coupled. One of the main limiting factors for the ODEPR measurements in the YL at high pressures is the strongly decreased the YL intensity at low temperatures. At normal pressure, when cooling the sample, the YL intensity increases. Under pressures of 5–10.8 GPa, the YL intensity decreases significantly upon cooling. ODEPR spectra of the undoped MOVPE GaN layer on sapphire measured in YL at 1.5 K at normal pressure showed resonance lines at $g_{\parallel} = 1.989$, and $g_{\parallel} = 1.952$ and a shoulder with $g_{\parallel} = 1.958$, respectively. At low temperatures under pressures of 5–10.8 GPa, a part of the YL intensity remains, but only the ODEPR line at $g_{\parallel} = 1.989$ is measured while that at $g_{\parallel} = 1.952$ disappears. The disappearing part of the YL is due to a donor–acceptor recombination from a DX-like donor, which is attributed to the oxygen on nitrogen sites (O_N) in agreement with theory and other experiments. © 2001 Elsevier Science B.V. Keywords: GaN; ODEPR; Yellow luminescence intensity; Pressure and temperature dependence

1. Introduction

GaN is an important material for opto-electronic applications in the visible and near UV spectral range [1]. In most nominally undoped metal organic vapor phase epitaxy (MOVPE)-grown GaN samples, an unwanted broad luminescence band centered around 2.2 eV, the so-called yellow luminescence (YL) is observed. The origin of this yellow luminescence has been actively debated [2–10].

The YL in n-type GaN was investigated under high hydrostatic pressure at room temperature by Suski et al.

[4]. A shift of the peak position of the YL with the shift of the conduction band up to a pressure of 20 GPa was found.

The aim of the present work was to investigate the optically detected electron paramagnetic resonance (ODEPR) and yellow luminescence intensity in wurtzite GaN under high hydrostatic pressures at low temperatures in order to obtain more information on the nature of the three ODEPR lines measured previously in the YL at ambient pressure and tentatively associated with shallow donors [10].

2. Experimental

Optically detected electron paramagnetic resonance measurements in the YL under pressures up to 7 GPa have been performed. A non-magnetic diamond anvil

cell was designed, into which microwaves in the 4 mm band (72 GHz) could be coupled.

All its parts were made of a CuBe alloy with 2% Be. The type IIa diamonds having a low luminescence were supported by B_4C disks to provide a maximum aperture for the microwaves, which reached the sample without significant attenuation. The gasket material was Inconel X 600 which distorted the magnetic field only slightly. The sample chamber had typically 250–300 μm diameter and 70 μm thickness. The pressure was measured using the ruby fluorescence method [11,12]. The use of liquid Ar as transmission media implied that a minimum pressure of few GPa had to be applied as the lowest pressure to completely seal the sample chamber. The pressure cell was placed into a He bath cryostat (1.5 K) and in a magnetic field up to 4 T. The optical excitation was done with a halogen or deuterium lamp followed by filters. The PL, which was corrected for the above band gap excitation intensity and for the contribution of the diamonds, was recorded through appropriate filters with a photomultiplier. The above band gap excitation intensity decreased with increasing pressure. The EPR was detected as a microwave-induced increase of the YL intensity.

The GaN layers, approx. 3 μm thick, were nominally undoped and grown with MOVPE on sapphire, the thickness of which was reduced to about 20 μm with mechanical polishing. The sample diameter was 200–250 μm .

The limitation to 7 GPa, of the ODEPR measurements, is due to the strongly decreasing YL intensity only. The high-pressure cell itself allows for ODEPR experiments up to pressures of 30 GPa [13].

3. Results

The YL measured at 295 K under pressure shows a blue shift and decreases in intensity, it is hardly measurable at 18 GPa [13]. This result is in agreement with the observations of Suski et al. [4].

The intensity of the YL increases when cooling to low temperature under ambient pressure. However, as seen in Fig. 1, it strongly decreases when cooling under pressure. Its spectral shape remains almost unchanged when changing the temperature. As the quenching effect increases, the higher the pressure becomes (see Fig. 2 for various pressures), while the spectral shape always remains unchanged (see Fig. 1).

Fig. 3 shows the ODEPR spectra measured at 72 GHz at ambient pressure using a large sample of an undoped MOVPE GaN layer on sapphire ($5 \times 10 \text{ mm}^2$) and optimal excitation conditions. The sample was not in a cavity but directly irradiated with the 4 mm microwaves. A very good signal-to-noise ratio could be achieved. The three resonances resolved, already measured previously

Fig. 1. PL signal of the YL at a pressure of 8 GPa for temperatures of 285, 205 and 10 K.

Fig. 2. Temperature dependence of the YL at different pressures.

Fig. 3. ODEPR spectrum for $B_{||}c$ measured in the YL at 72 GHz. The g -values of three resonance lines are shown.

[10], have been assigned to three shallow donors in Ref. [9] on the basis of a mapping investigation. The relative signal intensities of the line at $g_{||} = 1.989$ to that at $g_{||} = 1.952$ depend on the illuminated spot of the sample and can vary by as much a factor of 2. In Fig. 3, an average of the large sample is measured. The line at $g_{||} = 1.952$ was assigned to the residual donor ([3] and references therein).

Fig. 4 shows the results of the high-pressure ODEPR experiments. At ambient pressure, the two known resonances at $g_{||} = 1.989$ and $g_{||} = 1.952$ are clearly seen. The signal-to-noise ratio is much worse when measuring the ODEPR in the diamond anvil cell compared to Fig. 3, where a further resonance in the low-field shoulder of the line at $g_{||} = 1.952$ was detected at $g_{||} = 1.958$. Note that the magnetic field was corrected for the field shift by the pressure cell ($\sim 1\%$) and that the measurement time for each pressure was about 50 h. The relative signal intensity of the line at $g_{||} = 1.989$ to that of $g_{||} = 1.952$ is different from that of Fig. 3, since only a small piece of the sample with $\sim 250 \mu\text{m}$ diameter is used for the experiment with the diamond anvil cell, where the signal at $g_{||} = 1.952$ happens to be rather low compared to that at $g_{||} = 1.989$ [9]. The most important result is that the line at $g_{||} = 1.952$ previously ascribed to the residual donor disappears when pressure is applied, i.e. this donor belongs to that part of the YL which has a thermal barrier. The line at $g_{||} = 1.989$ does not disappear and it seems that the signal around $g_{||} = 1.958$ does not disappear either. However, due to the low signal-to-noise ratio, this cannot be stated with certainty. The line at $g_{||} = 1.989$ broadens somewhat under pressure.

One of the main limiting factors for the ODEPR measurements in the YL at high pressures is the significantly decreasing YL intensity at low temperatures.

Fig. 4. ODEPR signal in the YL at different hydrostatic pressures. The sample size is about $200 \mu\text{m}$ in diameter.

4. Discussion

At low temperatures, the relative signal intensity of the line at $g_{||} = 1.952$ to that at $g_{||} = 1.989$ changes under high pressures such that the line at $g_{||} = 1.952$ disappears which happens already at rather moderate pressures. This result shows that both ODEPR lines must belong to different recombination paths, in agreement with the result of the ODEPR mapping experiments [9].

The disappearance of the ODEPR line at $g_{||} = 1.952$ coincides with the disappearance of part of the YL by cooling to low temperatures under pressures of 5–10.8 GPa. Only part of the YL intensity remains. However, since the spectral shape of the YL remains almost unchanged at different temperatures and at pressures at least up to 8 GPa, both recombination paths of the YL must have very similar energy differences between donor and acceptor.

We propose that the disappearing recombination path of the YL involves a defect, which becomes a barrier at low temperatures and high pressures such as the DX-like donors [14] have. The disappearing part of the YL is due to a donor–acceptor recombination from a DX-like donor, which is attributed to O_N in agreement with theory [15] and other experiments [16].

Thus, we assign the residual donor to oxygen on nitrogen sites (O_N). It is well possible that Si_{Ga} is responsible for the shoulder at $g = 1.958$. An EPR study of Si-doped wurtzite GaN yielded $g_{||} = 1.9510$ in X-band [17]. It remains, however, unclear as to the nature of the other shallow donor with $g_{||} = 1.989$. It is only clear that this line cannot be the acceptor involved in the YL. Assuming recombination to the same acceptor, it will be a shallow donor with a very similar ionisation energy as O_N , perhaps within $\pm 50 \text{ meV}$.

Abstract

We investigated the structural defects in GaN grown by hydride vapor-phase epitaxy via flow-modulation growth technique. It is found that the structural defects decrease greatly from the initial layer ($10^{10-12} \text{ cm}^{-2}$) above substrate to the top layer (10^7 cm^{-2}). Optical differential interference contrast microscopy and atomic force microscopy observations show that the semiconductor layers have also good homogeneity and morphology. © 2001 Elsevier Science B.V. 1. Introduction

Structural quality of GaN films is of importance for the applications of this promising semiconductor. Significant progress in improving crystal quality has resulted in the development of blue LEDs, based on GaN, of high brightness [1,2]. However, the fabrication of high quality devices still demands high quality GaN. Hydride vapor-phase epitaxy (HVPE) has, therefore, attracted great interest, for it allows rapid growth of high-quality thick GaN epilayers. Recently, we developed flow modulation growth (FMG) techniques, in order to improve further, the crystalline quality of GaN films grown by HVPE [3,4]. In this study, the structure of the FMG-GaN films is investigated using transmission electron microscopy (TEM), cathodoluminescence (CL), optical differential interference contrast microscopy, atomic force microscopy (AFM), and X-ray diffraction (XRD).

2. Experimental procedure

The flow modulation growth is carried out at atmospheric pressure in a home-built vertical HVPE system [5]. The Ga source is GaCl in situ, formed upstream in the reactor by reacting the HCl gas with metallic gallium at 900°C and the N source is from NH₃. The growth of GaN is performed at 1050°C on a rotating substrate holder. More details of the growth parameters can be found elsewhere [4,5]. During growth, we periodically interrupt either NH₃ or HCl flow (flow of Ga source) but keep other parameters constant to modulate the GaN growth process periodically. When NH₃ flow is modulated, we call the growth process, NH₃ flow modulation and when HCl is modulated, it is called HCl flow modulation. For HCl flow modulation, the interruption of HCl flow is controlled for 30 min and the growth cycle of each sublayer is carried out for a time of 5–30 min. The NH₃ flow modulation is realized by switching off NH₃ for 20 s while keeping the growth cycle fixed at 15 s. All samples are grown on sapphire. Fig. 1 shows a schematic representation of the FMG process.

Fig. 1. The schematic representation of the FMG process.

The equipment used for TEM observations is a Philips CM 200. Low-temperature CL measurements were performed in a modified scanning electron microscope. A specific feature is the compilation of CL images, which map the local information at each sampling point. More details can be found elsewhere [6,7]. The surface morphology was investigated by optical differential interference contrast microscopy (ODICM) and AFM. These measurements were performed on a Nikon Eclipse E600 system for ODICM and on a Rastroscope 4000 for AFM. Crystallographic properties were evaluated by (0002) XRD measurements using a triple axis Siemens D5000 diffractometer system with a $\text{Cu K}\alpha_1$ ($\lambda = 1.54 \text{ \AA}$) radiation source operated at 45 kV and 20 mA.

3. Results and discussion

Fig. 2 shows the cross-sectional structure of GaN layers grown via FMG of HCl. There are four sublayers in the sample after three times of HCl interruptions. An abrupt reduction of structural defects can be found between two neighboring sublayers. Also, the defects are observed to decrease greatly from $10^{10-12} \text{ cm}^{-2}$ in the initial layer (a) above the substrate to 10^8 cm^{-2} in the upper sublayer (c) of the sample. A top view taken by CL shows that the pits at the top layer (d) are about 10^{7-8} cm^{-2} . We attribute the reduction of the defects to the “interruption” of the threading dislocation due to the interruption of the growth. During the interruption, defects such as dislocations may have time to move in the sublayers at such high temperature. Some may move to the edge of the films instead of threading into the subsequently grown sublayer. In addition, strain can relax completely for the interruption in an annealing process. Therefore, the abrupt decrease of defects can be observed and a top layer with much less defects can be obtained. A cross-sectional CL wavelength image of the FMG–GaN sample also shows that the homogeneity in the upper layers is improved [8]. This can also be explained by the interruption of threading defects and relaxation of strain. The improvements of both reduction of defects and homogeneity can also be observed in GaN layers grown via NH_3 flow modulation mode.

Fig. 2. TEM cross-sectional views of GaN grown via HCl flow modulation and a top view taken by CL: (a) is the initial layer, (b) the second sublayer, (c) the third sublayer layer, and (d) the top layer.

Fig. 3 shows the morphology of GaN layers taken by ODICM. There is a high density of cracks at the surface of GaN grown via HCl flow modulation while the GaN layers grown via NH_3 flow modulation exhibit almost crack-free surfaces. More microscopic views taken by AFM find that the former samples have large values of roughness ($\sim 4 \text{ nm}$) while the latter ones have smooth surfaces at atomic level ($0.5\text{--}0.9 \text{ nm}$). Considering the difference between the two FMG processes, we explain the different morphologies as follows: the interruption of HCl flow for 30 min at the growth temperature exposes the as-grown GaN to the corrosive ambient. This,

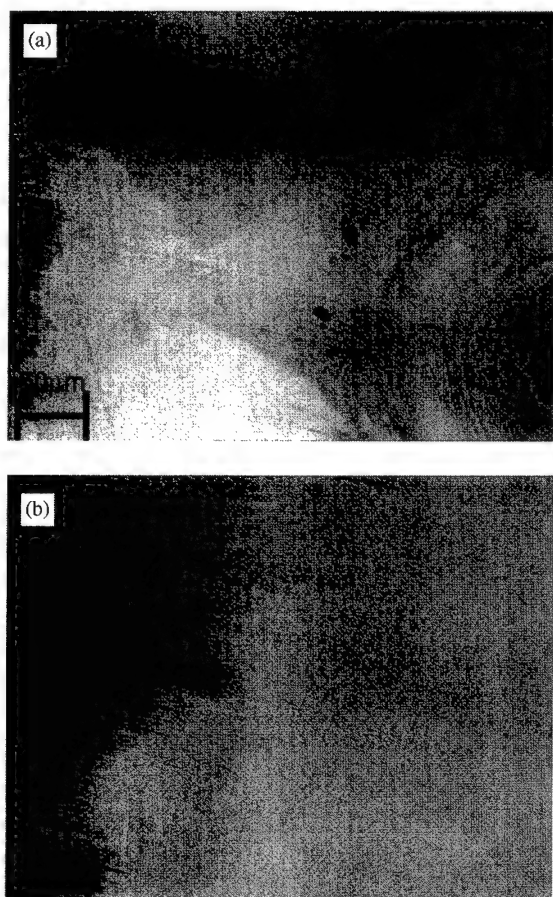

Fig. 3. The morphology of GaN grown via HCl flow modulation (a) and NH_3 flow modulation (b).

therefore, results in heavy etching of the surface of as-grown GaN so that it causes poor morphology in the subsequently overgrown layers and finally in the top layer. The smooth surface of GaN layers grown via NH_3 flow modulation is due to the Ga-rich growth conditions. The morphology of the lateral overgrown GaN is related to the local balance of III/V ratio in the gas phase and the density of Ga and N bonds [9]. Since the reduced N supply can greatly enhance the diffusion of Ga adatoms [10], the Ga diffusion on the as-grown plane will occur more easily. As a result, the lateral overgrowth will be greatly enhanced whereas the vertical growth could be suppressed, and a smooth surface is thus, obtained.

X-ray rocking curve measurements are performed. The full-width at half-maximum (FWHM) of the GaN (0002) X-ray rocking curves are 309 arcsec for GaN grown via HCl flow modulation and 335 arcsec for the sample via NH_3 flow modulation, respectively. As a reference sample, GaN grown directly on sapphire

without any flow modulation is also measured. The FWHM of its (0002) rocking curve is 423 arcsec. Since the FWHM is a measure of crystalline quality, it could be concluded that both the flow modulations cause improvements of the crystalline quality, which is in agreement with the above results taken by TEM and CL.

4. Summary

The structure of GaN layers grown by HVPE via HCl/ NH_3 FMG is investigated with TEM, CL, ODICM, AFM, and XRD. It was found that defects decrease greatly from $10^{10-12} \text{ cm}^{-2}$ in the initial layer above substrate to 10^7 cm^{-2} in the top layer. Also, improved homogeneity is found in the upper layers of samples grown via both the flow modulations. We attribute the improvement of crystalline quality to the interruption of threading dislocations and the relaxation of strain. GaN layers grown via HCl flow modulation exhibit rough surfaces while the layers via NH_3 flow modulation have atomic smooth surface. The former is due to strong etching and the latter is attributed to enhanced Ga diffusion.

Characterization of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers grown by molecular beam epitaxy

Hyonju Kim*, T.G. Andersson

Applied Semiconductor Physics, Department of Microelectronics and Nanoscience, Chalmers University of Technology and Göteborg University, S-412 96 Göteborg, Sweden

Abstract

Epitaxial $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers were grown by RF-plasma assisted molecular beam epitaxy. The Al mole fraction were derived from X-ray diffraction $\omega/2\theta$ symmetric reflections as $x = 0.11, 0.23$, and 0.29 , respectively. During the secondary ion mass sputtering analysis we found an interesting feature, expressed as *preferential sputtering in local areas*. A detailed atomic force microscope study revealed that this preferential sputtering caused a long tunnel penetrating the layer down to the sapphire substrate, and consequently gave rise to the abnormal increase of the O and Al content in the SIMS profile of the grown sample. The character of the long tunnel formed along the growth direction and the estimated density of the tunnels ($2 \sim 3 \times 10^6 \text{ cm}^{-2}$) suggest that the origin of the preferential sputtering can be the nanopipes centered at the screw dislocations. © 2001 Elsevier Science B.V. 1. Introduction

Due to their direct wide band gap spanning from 3.4 to 6.2 eV, $\text{Al}_x\text{Ga}_{1-x}\text{N}$ alloys have been a growing research topic towards the applications in optoelectronic devices such as photodiodes, light emitting and laser diodes in the visible to ultraviolet wavelength region. For the realization of such devices with good performance, it is essential to grow thick $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer with a high AlN mole fraction x along with good crystalline quality. The crystalline quality of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers has been improved significantly by growing them on high-temperature grown thick GaN layer. In addition, low temperature grown interlayers (ILs) in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer have been found to decrease the density of threading dislocations, resulting in considerably improved crystalline quality [1–6]. However, with increased AlN mole fraction, the layer suffers the increasing in-plane tensile strain between the layer and

substrates and/or buffer layers, which increases the dislocation density and could ultimately cause cracks to spread through the layer. To overcome these problems it is indispensable to develop optimized buffer layer structures, which can mitigate the strain in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers.

On the other hand, aluminum is known to react preferably with oxygen, resulting in high O contamination in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ alloys [7,8]. The incorporation of O in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ should be carefully kept in mind due to the induced deep levels (DX-center) in the band gap with increasing Al content [9]. In the previous report [10], we found that the presence of a small amount of Al (0.03~1%) in GaN is responsible for the additional O incorporation in the layer. However, the mechanism of how Al facilitates the O incorporation in the layer is still unknown and need to be studied more carefully.

In this study, we fabricated $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers with high Al content, i.e. above 10%. To obtain the concentration-depth profile of Al and O in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers, we carried out secondary ion mass spectrometer (SIMS) analysis using Cs^+ ion as a primary beam. Since we, in an earlier investigation, found a quite high oxygen

E-mail address: hyonju@fy.chalmers.se (H. Kim).

concentration in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers with $x \leq 1\%$, a new set of samples was made with higher Al content and also with changed etching procedures for the substrate preparation. This new series of samples exhibited much reduced oxygen concentrations compared to the previous samples. Although it was not feasible to extend the obtained relationship between O and Al at the lower Al content ($\leq 1\%$) to higher Al mole fraction in this report, we found several interesting features during characterization of the grown structures.

2. Experiments

Epitaxial $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers were grown on (0001) sapphire substrates using RF-plasma assisted molecular beam epitaxy (MBE) technique. The substrates were ultrasonically degreased in trimethylethylene, acetone and methanol for 5 min in each step. With the purpose to remove oxides, the substrates were etched in two steps, $\text{HNO}_3:\text{H}_2\text{SO}_4$ (1:1) for 10 min, and then $\text{HCl}:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ (5:3:3) for 3 min. Before growth, the substrates were outgassed at 700°C for 40 min in the growth chamber. Then the temperature was lowered to 600°C for a Ga-cleaning process to remove surface contaminants such as O- and C-compounds [11]. The process was repeated three times by evaporating the deposited Ga metals at elevated temperatures ($\sim 750^\circ\text{C}$). Subsequently, nitridation was carried out at 700°C for 40 min, and followed by the growth of thin ($\sim 10\text{ nm}$) AlN buffer layer at 650°C . To improve the crystalline quality, a thick GaN layer ($0.6\text{ }\mu\text{m}$) was grown at 760°C before the growth of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer. Finally $0.6\text{ }\mu\text{m}$ thick $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers with different Al mole fraction were grown at the substrate temperature of 760°C . The RF-plasma power and N_2 gas flow rate were kept at 500 W and 2.3 sccm, respectively, during the growth of GaN and $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers.

To investigate the crystalline quality and derive Al mole fraction, X-ray diffraction (XRD) measurements were performed in a multi-crystal high resolution Philips Extended X-pert Material Research Diffractometer. To improve the resolution we used an analyzer crystal for all the measurements presented in this study. An atomic force microscopy (AFM) (Dimension 3000, Digital instruments) was also used for surface characterization of the grown samples.

In order to determine the distribution and concentration of oxygen impurities and aluminum in the layer, a Cameca IMS-6F SIMS instrument operating at a pressure of 1×10^{-9} mbar was used. In order to analyze the O concentration, we selected a Cs^+ primary beam, which was focused to a $25\text{ }\mu\text{m}$ diameter with an impact energy of 14.5 keV and a current of 80 nA. The primary beam was rastered over an area of $250 \times 250\text{ }\mu\text{m}^2$ and the secondary negative ions (O^- , Al^- , GaN^- , etc.) were

collected from the central area (approximately $50\text{ }\mu\text{m}$ in diameter) to avoid the effect from crater edges. The details for a standard sample of O implantation used for quantification were described elsewhere [10].

3. Results and discussion

Fig. 1 displays the XRD $\omega/2\theta$ symmetric (00.2) reflections for the three heterostructures of $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ grown at different Al-source temperatures while keeping the same Ga/N flux ratio. Using an analyzer crystal instead of a single slit, we could observe a well-separated $\text{Al}_x\text{Ga}_{1-x}\text{N}$ alloy peak from that of GaN as represented in the figure. In the assumption that the $0.6\text{ }\mu\text{m}$ thick $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers grown on GaN are fully relaxed and that the Vegard's law is valid, the Al mole fraction was derived from the symmetric reflections as 11%, 23%, and 29%, respectively. It is clear that the diffraction peak from alloy is shifted towards higher angle with increasing Al content, denoting a decrease in lattice constant c . It should be noted that the Al mole fraction of the sample with the highest concentration, #924, was determined by an average from the two alloy peaks as can be clearly seen in the Fig. 1.

A possible origin for the splitting of the alloy peak (#924) can be explained as a phase separation into two different compositions of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer, as also observed by Görgens et al. for InGaN alloys [12]. They found two wurtzite phases of different indium composition in the layer. One was a pseudomorphically grown part with In mole fraction of 17%, the other a fully relaxed part with a higher In concentration of 28%. However, they could only observe the separation in asymmetric reflections because both phases had the same lattice constant c within the given resolution. In

Fig. 1. HRXRD $\omega/2\theta$ symmetric (00.2) reflections for $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ heterolayers with different Al mole fraction grown on (0001) sapphire substrates. The XRD patterns of #922 and #923 were shifted along the y-axis for clarity.

our case, although we observed a clear separation in symmetric reflection, it is not possible to clarify the strain state, i.e., whether the layer is fully, or partially relaxed, or if it is pseudomorphically grown, etc. In order to fully understand these features, it will be necessary to proceed the investigation by performing the reciprocal space mapping for the asymmetric reflections.

The oxygen impurity concentrations in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layers were determined from SIMS analysis and compared with the previous results obtained for lower Al concentrations ($x \leq 1\%$) as represented in Fig. 2. For the low Al-content we determined the empirical relation between the Al and O impurity concentrations as $C'_\text{O}/C'_\text{O}^b = 3.8 \times (C_{\text{Al}}/C_{\text{Al}}^b)^{0.27}$. In the formula, C'_O (cm^{-3}) and C_{Al} (%) represent total O concentration and Al mole fraction, respectively, and the constants were given as $C'_\text{O}^b \sim 10^{19} \text{ cm}^{-3}$ and $C_{\text{Al}}^b \sim 1\%$. As described in the previous report [10], we expect this empirical relationship can be used for the future work to elucidate the role of Al in the additional incorporation of O in the layer. On the other hand, the new set of samples with higher Al content exhibited much reduced oxygen concentrations compared to the previous samples. This reduced O level could arise from the changed etching procedures used for the substrate preparation. However, a further investigation will be needed before we discuss the effect of this chemical etching process here.

During the SIMS analysis we found an interesting feature, which we express as *preferential sputtering in local areas*. Fig. 3 shows a typical SIMS depth profile of the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ heterostructure of the sample #923. As seen in the figure, O and Al concentrations exhibited abnormal increase from the middle of the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer for oxygen and from the interface of

$\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ for aluminum, respectively. A similar feature was observed for all three samples investigated in this work. After the examination of the surface inside the crater using optical microscopy and AFM, the origin of the sudden increase of the signal was found to be due to a preferential sputtering in local areas, which gave rise to a long 'tunnel' reaching the sapphire (Al_2O_3) substrate already in the middle of the SIMS sputtering process. Thus, these 'tunnels' are considered to be responsible for the observed abnormal increase of O and Al levels in the profile as given in Fig. 3. It also should be noted that due to the high Al content in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer, the effect on Al concentration from the holes penetrating the layer are invisible in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer, while the O level already started to increase. An AFM image for one (#924) of the samples is given in Fig. 4, which clearly demonstrates holes of micron size threading the layer. The image was scanned on the surface where the ion sputtering was stopped in the middle of the GaN layer. A more-detailed study shows that the density of holes was slightly higher at the substrate surface ($3 \times 10^6 \text{ cm}^{-2}$) compared to the middle of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer ($2.1 \times 10^6 \text{ cm}^{-2}$). The hole-size was found to grow gradually as the ion sputtering proceeded towards the substrate. The diameter of the holes was estimated to be in the range $0.5 \sim 0.8 \mu\text{m}$ in the middle of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer, but with a larger size variation at the near substrate interface ranging $0.5 \sim 3 \mu\text{m}$.

Fig. 2. Oxygen impurity concentration as a function of Al mole fraction in a logarithmic scale, determined from SIMS analysis. Samples with low Al content ($\leq 1\%$) are represented with closed circles, and high Al content ($\geq 10\%$) with squares. For details of the fitting (dashed line) at low Al content the reader is referred to Ref. [10].

Fig. 3. Typical SIMS depth profile for the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ (0.6/0.6 μm) grown by the MBE technique.

Fig. 4. AFM images of the surface after the SIMS sputtering was stopped in the middle of the GaN layer (#924). The image area is $10 \times 10 \mu\text{m}^2$.

The GaN and related alloys grown on sapphire substrates typically exhibit dislocation densities of $10^9 \sim 10^{10} \text{cm}^{-2}$, due to the large difference in lattice parameters and thermal expansion coefficient. While most of these dislocations are of pure edge type, some groups observed another type of defect, referred to as *nanopipes* or *micropipes* found at the cores of screw dislocations. Qian et al. [13–15] found tunnel-like defects, termed as open-core screw dislocations, aligned along the growth direction (*c*-axis) of the crystal and penetrating the entire GaN epilayer [14]. Their microscopic observations revealed the density of such nanopipes to $10^5 \sim 10^7 \text{cm}^{-2}$. If the origin of the preferential sputtering occurred during the SIMS analysis is associated with these nanopipes centered at the screw dislocations, the estimated hole-density ($\sim 10^6 \text{cm}^{-2}$) in this study is in a good agreement with their observations. In addition, the character of open-holes of nanopipes renders larger area exposed to the primary ion beams during the SIMS analysis. Therefore, the holes can be etched faster than other areas which explains the micron size of holes observed in our samples.

4. Conclusions

We have grown $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ heterostructures on sapphire (0001) substrates using the RF-plasma assisted MBE technique. The Al mole fraction was determined from HRXRD $\omega/2\theta$ symmetric reflections under the assumption that the alloy layer was fully relaxed and that the Vegard's law is valid. We found a splitting in the diffraction peak from $\text{Al}_x\text{Ga}_{1-x}\text{N}$ layer

with the highest Al content ($x = 0.29$), which can be ascribed to the phase separation into two different compositions, mostly with different Al contents.

The SIMS analysis revealed that after the change of the chemical etching process for the substrate preparation the oxygen impurity level was reduced compared to the previous samples. However a detailed investigation has yet to be performed to clarify the effect of the changed chemical etching process.

We found an interesting feature, expressed as 'preferential sputtering in local areas', during the SIMS analysis. The AFM investigation along with the optical microscope revealed that this preferential sputtering caused a long 'tunnel' (from submicron to several micron in diameter) penetrating the layer down to the substrate, which consequently gave rise to the abnormal increase of O and Al content in SIMS profile for the grown layers. The character of the long tunnel formed along the growth direction and the observed similar density of the tunnels ($2 \sim 3 \times 10^6 \text{cm}^{-2}$) suggest that the origin of the preferential sputtering or of the tunnels can be the nanopipes centered at the screw dislocations.

AFM study of lattice matched and strained InGaAsN layers on GaAs

Yeonjoon Park*, Michael J. Cich, Rian Zhao, Petra Specht,
Henning Feick, Eicke R. Weber

Department of Materials Science & Engineering, U.C. Berkeley, Berkeley, CA 94720, USA

Abstract

We studied strained & lattice matched InGaAsN, InGaAs, and GaAsN layers, grown on GaAs substrate with gas source molecular beam epitaxy. Nitrogen concentration and lattice-matched condition have been established from Vegard's law with X-ray diffraction. Atomic force microscope measurement, at 22-monolayer thickness, shows different growth mechanism for each composition. Especially, a mesh-like surface morphology of lattice matched InGaAsN has been revealed in this study. © 2001 Published by Elsevier Science B.V.

Keywords: InGaAsN; GS-MBE; AFM; Laser diode

1. Introduction

Since the first proposal by Kondow et al., [1], GaAsN and InGaAsN layers on GaAs substrate have attracted a lot of research interest due to its application for the long wave laser diode with an excellent high temperature performance. Shan et al. [2], explained the reduction of band-gap of GaAsN alloys with the strong perturbation of N atoms to the conduction band, which causes the splitting of the conduction band into two sub-bands. Laser diode operation at 1.3 μm wavelength for the optical fiber communication, has been demonstrated by several groups, including Kondow et al. [1,3], Steinle et al. [4], Livshits et al. [5] and Mars et al. [6]. Especially, Kitatani, Kondow et al. [7] fabricated 1.3 μm GaInNAs/GaAs single quantum well laser diode with a high characteristic temperature over 200 K. There have been only a few studies about the growth mode and the surface morphology of (In)GaAsN alloys. R.M. Feenstra et al. studied the local electric properties of GaAsN alloy with scanning tunneling microscope (STM) on the planar surface [8] and in cross-section [9]. Auvray et al. studied the growth mode of GaAsN on a 2° miscut

GaAs surface with different nitrogen concentration, using atomic force microscope (AFM) [10]. They found that the growth mode of GaAsN layer on vicinal GaAs substrate changes from a bunched step/terrace structure to indistinct 2D-nucleation structure when increasing the N content.

In our study, we tried to compare the growth mode differences of important layers, GaAs_{0.98}N_{0.02}, In_{0.4}Ga_{0.6}As, and In_{0.66}Ga_{0.94}As_{0.98}N_{0.02} layers on GaAs, which are used for 1.3 μm laser diode applications, with AFM and high resolution X-ray diffraction (HRXRD).

2. Experimental procedure

Gas source molecular beam epitaxy (GS-MBE) with DC nitrogen plasma source has been used to grow nitrogen-containing layers [11,12]. Since the kinetic energy of nitrogen plasma of our DC plasma source is determined by the gas-flow itself, it causes very low plasma damage to GaAs surface. A solid arsenic source (As₄) was used to give a beam equivalent pressure (BEP) of 2×10^{-5} Torr. The Ga vs. As BEP ratio was set to 1:20. Si doped n-GaAs substrates were used and the temperature of the substrates were monitored with

diffuse reflective spectroscopy (DRS), whose long-term measurement error is $\pm 1^\circ$. All of the GaAs substrates were outgassed at 200°C and oxide removal was performed at 570°C in the MBE chamber. After the oxide removal, a rather spotty RHEED pattern was observed. A GaAs buffer layer of 200 nm-thickness was grown to achieve a higher-quality starting plane with a very sharp, clear, streaky (2×4) RHEED pattern. After the growth of the GaAs buffer layer, the substrate was cooled down to 500°C to incorporate indium, since the InAs desorption temperature is around 515°C . After all the buffer layers were prepared with the same condition, 22 mono-layers of a bare GaAs, $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$, $\text{GaAs}_{0.98}\text{N}_{0.02}$, or $\text{In}_{0.06}\text{Ga}_{0.94}\text{As}_{0.98}\text{N}_{0.02}$ were grown with specific control parameters, respectively. The growth rate of $0.75 \mu\text{m/h}$ was used. Capping layers were not grown in order to reveal the top surface for AFM studies. Direct after the growth of the thin layers, the substrate was cooled down for 10 min. in As over-pressure and then transferred to the atmosphere for AFM measurement. Park Scientific Instruments AutoProbe VP system was used for AFM studies. Since AFM measurements were directly performed within 10 min. after the growth, the effect of gallium-oxide formation was minimized. As a reference, the bare GaAs surface did not show any effect from the oxide in AFM images. $10 \mu\text{m} \times 10 \mu\text{m}$, $4 \mu\text{m} \times 4 \mu\text{m}$, and $2 \mu\text{m} \times 2 \mu\text{m}$ scan area

were used for AFM studies. We will write $10 \mu\text{m} \times 10 \mu\text{m}$ area scan as $10 \mu\text{m}$ scan for convenience.

To incorporate the right amount of indium and nitrogen, $0.5 \mu\text{m}$ thick layers were grown on GaAs to fabricate fully relaxed layers for symmetric (004) X-ray diffraction scan. Nitrogen concentration and lattice-matched condition were obtained from these preliminary experiments (Fig. 1(a)).

The symmetric (004) scan, and asymmetric (224) and (113) normal scans did not show any peak from the thin 22-monolayer-thick epi-layer. However, (113) Ω^+ , (224) Ω^+ normal scans with the detector at a glancing angle of 1.6° and 6.6° from the surface, have very strong sensitivities for the surface layers and they show clear epi-layer peaks (Fig. 1(b) and (c)).

3. Results and discussion

Fig. 1(a) shows the (004) symmetric diffraction peak of a $0.5 \mu\text{m}$ thick InGaAsN layer with 1.5% nitrogen concentration on a GaAs substrate. 1.25 sccm of nitrogen flow and 20 mA of plasma current were applied and the indium source temperature was controlled between 715°C and 735°C . The FWHM of the substrate peak was 0.015° and that of lattice matched InGaAsN was 0.025° . The layer with the least lattice mismatch of

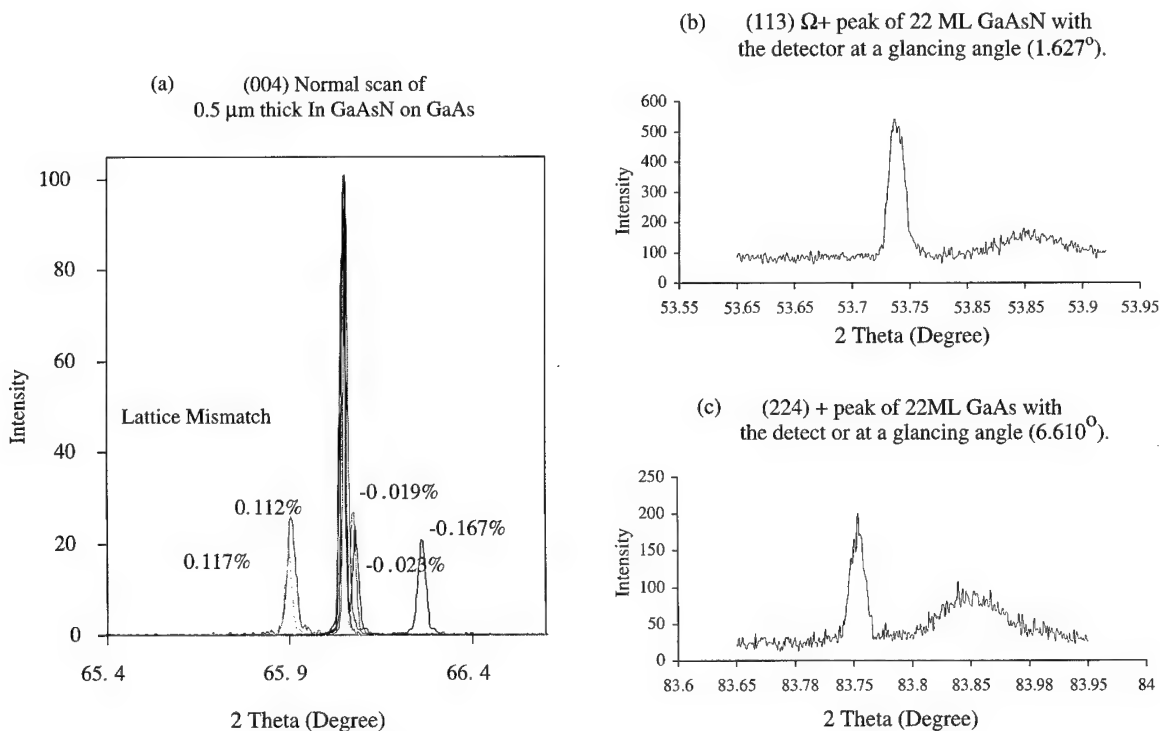

Fig. 1. High resolution X-ray diffraction scan.

–0.019% has a critical thickness far above 1 μm according to the Matthews–Blakeslee model. After lattice matched conditions were established with the different nitrogen concentration, these conditions were applied to the growth of the thin layer of 22-monolayer thickness. Assuming the coherently grown layer model, in-plane and out-of-plane lattice constants were obtained from (113) Ω^+ , (224) Ω^+ scans (Fig. 1(b) and (c)). An iterative method was used to include plane tilt angle $\Delta\tau$. Nitrogen concentration was obtained from Vegard's law.

AFM measurements of 10, 4, and 2 μm scans, show various growth modes (Fig. 2). AFM images of bare GaAs show a couple of bunched steps and its root-mean-square (RMS) roughness of 4 μm scan was 5.3 \AA . The measured step height was less than 15 \AA . The contrast is maximized to reveal detailed structures. Oxidation of GaAs is not observed. The white area with higher height at the left and right edges of the 10 μm image is the effect of the AFM tube scanner curvature correction. This effect is not observed in other images of smaller scan area.

$\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ shows the self-organized circular island growth mode, which is typically used as quantum dots.

The RMS roughness of the 4 μm scan is 80 \AA . The average island size is 75 nm and the average island height is 130 \AA . However, some of the islands were higher than 200 \AA , exceeding the intended layer thickness. The general island shape is like an isolated circular hemisphere.

GaAsN with 2% of nitrogen shows μm -size strained hills and small-island-growth on top of the hills (Fig. 2, 10 and 4 μm images). We believe the modulated hill structure corresponds to the bunched step-terrace structures on 2° miscut GaAs substrate, which is observed by Auvray et al. [10]. The size of the modulated hill structure is of the order of a few μm in lateral direction and 50 \AA in height. The RMS roughness of the 4 μm scan was 21 \AA . The existence of small islands with an average height of 20 \AA on the hills indicates that the growth mode may change from the layer-by-layer to the island growth. The black holes in the 10 μm AFM image were confirmed to be AFM tip indents formed in the initial approach. GaAsN is under tensile stress on a GaAs substrate and becomes softer than other layers. We confirmed that the AFM tip in the initial approach could generate crack-like indents on a GaAsN layer in different areas.

Fig. 2. AFM images of epi-layers (22 monolayer thickness) on GaAs.

The most interesting AFM data were obtained from the lattice matched $\text{In}_{0.06}\text{Ga}_{0.94}\text{As}_{0.98}\text{N}_{0.02}$ layer grown at 0.75 $\mu\text{m}/\text{h}$ growth rate. 10 and 4 μm scans show flat mesh-like networked structures. The RMS roughness of 4 μm scan is 15 Å. This small number indicates the lattice-matched surface is flatter than other lattice mismatched layers even though there are a lot of meshed structures inside. However the growth mode is not a layer-by-layer growth. The measured average height of the mesh was 25 Å. We propose the following possibilities. (1) Local islands are formed first and these islands are connected together to create meshed structures. Since the surface adatom diffusion length determines the morphology, this indicates that the diffusion length of InGaAsN is smaller than that of GaAs or GaAsN. (2) Composition variation occurred during the growth and/or spinodal-decomposition-like composition-modulation-mechanism generated the meshed structure during the growth and cooling down process lasting 10 min. If this is a result of voluntary evolution into a composition modulation, such a meshed structure could be understood by a total energy argument. By adopting a large indium atom in the tensile convexed hill top region of the meshed structure and smaller nitrogen atom in the compressive concave bottom of the valley, the total strain energy of the epi-layer could be reduced. In this case, a faster growth rate and the reduction of the growth interruption should remove the meshed structure and bring back the layer-by-layer growth.

On the other hand, such a meshed structure can be utilized to confine carriers into small regions like quantum dots, so that we may raise the characteristic temperature of laser diodes even higher for a better performance at the high temperature. As a reference, Mars et al. [6] found the faster growth rate above 2 $\mu\text{m}/\text{h}$ gives better crystal quality of thick InGaAsN layers.

In summary, we studied the growth modes of thin epi-layers of GaAs, $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$, $\text{GaAs}_{0.98}\text{N}_{0.02}$, and $\text{In}_{0.06}\text{Ga}_{0.94}\text{As}_{0.98}\text{N}_{0.02}$, which were grown on GaAs

substrates. Layer by layer growth of GaAs, circular island growth of InGaAs, modulated hill and small island formation of GaAsN, and the meshed network formation of InGaAsN were observed with AFM.

Abstract

The in-plane and in-depth characteristics of the GaN and InGaN epilayers grown by the metalorganic chemical vapour deposition (MOCVD) on three different substrates (sapphire, SiC and bulk GaN) are evaluated. Relatively large intensity fluctuations of “edge” GaN and InGaN emissions are observed and are related to the details of the micro-structure of the GaN and InGaN films studied. The experiments indicate a nonuniform defect distribution in all types of the MOCVD films studied. In particular, the decoration of structural defects with impurities, an increased defect accumulation at the interfaces and a surprisingly small influence of the micro-structure on the in-plane homogeneity of the yellow band cathodoluminescence emission are observed. © 2001 Elsevier Science B.V. 1. Introduction

The range of GaN-based optoelectronic devices emitting amber–violet light was commercialised. Despite wide range applications, their operation is not understood yet. Relatively high efficiency of light emission is observed for heavily defected structures, with dislocation densities typically in the range of 10^8 cm^{-2} . A surprisingly low efficiency of nonradiative recombination at the dislocations is related to the strong localisation effects present in the InGaN-based light emitting devices [1]. Strong localisation effects are commonly related to either details of the micro-structure of the GaN, InGaN and AlGaIn layers [2], or to the In fraction fluctuations in the InGaIn [1]. Our recent

experimental results indicate that strong compensation effects are also present in the GaN samples, which results in the appearance of strong local electric fields and thus can also contribute to the localisation effects observed in the samples studied [3,4]. The role of the latter effect is evaluated in the present study.

2. Experimental

The (0001)-oriented n-type GaN films were grown by metalorganic chemical vapour deposition (MOCVD) on three different substrates—sapphire, SiC and bulk GaN. The latter layers are called the homoepitaxial films. Two InGaIn (3% of In)-on-GaN on sapphire samples, also grown by the MOCVD, were studied for comparison.

The photoluminescence (PL) experiments were performed at 2 K. The 351 nm UV line of an Ar⁺ laser was used for the PL excitation. The micro-PL spectra were

E-mail address: godlew@ipfan.edu.pl (M. Godlewski).

measured in a Renishaw micro-Raman system with a resolution of 1.6 meV using a polarised 325 nm excitation at an excitation power density of 120 kW/cm². The PL emission spectra at single locations and emission maps, that is spatial distributions of emission from the sample, were taken at a spatial resolution typically of the order of $2 \times 2 \mu\text{m}$ and were measured at room temperature.

The cathodoluminescence (CL) and scanning electron microscopy (SEM) measurements were performed at 4 K on LEO 1550 computer controlled field emission scanning electron microscope, equipped with monoCL2 set-up for the CL studies of Oxford Instruments and helium temperature gas flow stage. In addition to a conventional CL, spot-mode CL, scanning CL and depth-profiling CL measurements were also performed. The latter experiment was carried out to estimate in-depth characteristics of the MOCVD structures. In this experiment, we varied an accelerating voltage, thus varying the penetration range of primary electrons [5].

3. Results and discussion

Four PL emission bands were observed in all the GaN samples studied; showing very different relative intensities and also different spectral widths. These are the excitonic edge PL, a structured shallow donor–acceptor pair (DAP) PL at about 3.2 eV, the blue band DAP PL at about 3.0 eV and the yellow DAP PL at 2.2–2.3 eV. The origin of these PL bands is described elsewhere [6] and will not be discussed here. Only for the homoepitaxial films, a well-resolved edge PL was observed. This PL was dominated by the recombination of excitons bound at neutral donors (DBE PL) at 3.472 eV and free excitonic (FE_A) PL at 3.478 eV. With increasing temperature, additional FE PL at 3.484 eV (FE_B PL) was also resolved.

We performed detailed micro-PL, CL, scanning CL and depth-profiling CL investigations to evaluate in-plane and in-depth characteristics of the PL emissions. In Fig. 1, we show depth-profiling CL spectra observed for the GaN films grown on sapphire. Similar results were obtained for all the samples studied. The excitonic edge PL emission is not observed from heavily defected interface-close regions of the structures and also is fairly weak when excited from surface-close regions of the films. Three defect-related PL emission bands also show depth-dependent properties. Whereas, the yellow DAP PL and the shallow DAP PL are the strongest when excited from interface-close regions of the films, the blue DAP PL is the strongest from the surface-close regions of the samples.

In our previous scanning CL investigations, we have shown the direct link between the micro-structures of the GaN epilayers and the in-plane fluctuations of the edge

Fig. 1. The in-depth variations of the CL in the GaN/sapphire MOCVD-grown structure, measured at a temperature of 4 K at different accelerating voltages.

Fig. 2. The in-plane variations of the intensity of the edge CL emission in the GaN/GaN sample, measured at 4 K, 10 kV accelerating voltage and at 2000 \times magnification.

PL intensity [7]. From the SEM investigations, we could correlate the observed changes of the intensity of the excitonic edge PL with a granular micro-structure of the MOCVD epilayers. A very improved micro-structure, observed for the homoepitaxial GaN layers, results in different in-plane variation of the PL. Large areas of atomically flat surfaces are observed in the SEM study. These areas are interrupted by growth steps, often of the monolayer size. We found relatively few micro-defects, such as dislocations or hexagonal pits, commonly observed in other MOCVD-grown samples [8,9]. Fig. 2 shows a decoration of these steps with donor impurities. We observed a very enhanced DBE PL from the growth step regions of the layers, shown as bright regions in Fig. 2. A relatively weak FE PL is observed from these areas, which indicates that the FE excitons can diffuse to the growth step regions and be trapped there.

Fig. 3 shows another type of defect-related inhomogeneity, which we observed in homoepitaxial films. A very enhanced DBE excitonic PL is observed from the region of a large hexagonal pit. Also, the shallow DAP

Fig. 3. The in-plane fluctuations of the DBE PL intensity in the GaN/GaN sample, measured at 4 K, 10 kV accelerating voltage, at 40 000 \times magnification and from the region close to a large hexagonal pit.

Fig. 4. The micro-PL maps of the excitonic edge PL (a) and the shallow DAP PL (b) observed for the InGaN-on-GaN/sapphire structure.

PL is enhanced (not shown) but two “deep” DAP PL emissions are weak. The enhanced edge PL at the hexagons were also observed for the HVPE-grown GaN samples and explained by doping nonuniformities [9].

In the case of the InGaN epilayers, the main mechanism of the PL intensity inhomogeneities was related to variations of the In fraction in the film plane [1]. If so, we should observe enhanced variations of the intensity of the edge PL and also of the other PL emissions and corresponding shifts of their spectral positions. Such enhanced PL intensity variations are not observed in the InGaN layers with small In fraction studied by us. In Fig. 4, we show maps of the PL intensity changes observed in the micro-PL study with the detection set at the excitonic and shallow DAP PL emissions. The data indicate that there is anti-correlation between the total intensity of the “edge” excitonic PL and the intensity of the shallow DAP PL emission. We explain such anti-correlation by inhomogeneities in defect distribution.

We also observed that the yellow PL is surprisingly in-plane homogeneous in the GaN layers. In the case of the GaN samples, the yellow PL is coming mostly from the regions close to the interface with substrates. We observed a different situation in the InGaN-on-GaN samples. The depth-profiling experiments for the InGaN samples indicate that this PL also comes from the upper layer of the structure, close to the InGaN-to-GaN interface. This is likely due to the fact that this layer is strained and thus is of a lower structural quality. Such anti-correlation, between the strength of the yellow PL and the sample quality, was observed by us in several cases [10].

4. Conclusions

The present studies demonstrate very complicated in-plane and in-depth variations of the defect-related PL emissions. These variations can only be partly explained by the micro-structure of the samples. They also relate to large inhomogeneities in the defect distribution. Our studies indicate that these nonuniformities in doping can also result in enhanced carrier/exciton trapping/localisation and can explain some of the observed in-plane and in-depth characteristics of the PL emissions.

Abstract

By using scanning electron microscopy and cathodoluminescence (CL), a decrease in radiative efficiency of GaNP alloy with increasing N content is seen due to the formation of structural defects. The defect formation is attributed to relaxation of tensile strain in the GaNP layer, which is lattice mismatched to GaP substrate. Several types of extended defects including dislocations, microcracks and pits are revealed in partly relaxed $\text{GaN}_x\text{P}_{1-x}$ epilayers with $x \geq 1.9\%$, whereas coherently strained layers exhibit high crystalline quality for x up to 4%. According to the CL measurements, all extended defects act as competing, non-radiative channels leading to the observed strong decrease in the radiative efficiency. From CL mapping experiments, non-uniformity of strain distribution around the extended defects is partly responsible for the broadening of the photoluminescence (PL) spectra recorded in the macro-PL experiments. © 2001 Elsevier Science B.V. 1. Introduction

Incorporation of a small amount of N in GaP is expected to cause a transition from an indirect band-gap in GaP to a direct band-gap in GaNP alloy [1,2], leading to much increased efficiency of light emission desirable for optoelectronic applications. Indeed, an increase in photomodulation signal associated with absorption edge of the alloy [2] and an enhancement in photoluminescence (PL) intensity [3] has been reported for $\text{GaN}_x\text{P}_{1-x}$ with $x < 1.3\%$. On the contrary, a further increase in N content causes rapid degradation of the optical quality evident from a strong PL quenching accompanied by a broadening in PL line width. Even though the exact mechanism of this degradation is not known so far, the effect has been naturally attributed to the formation of

some non-radiative (NR) defects in the alloy with high N content. The formation of NR defect can be partly caused by relaxation of tensile strain in the GaNP layer, which is lattice mismatched to GaP substrate [4]. In this paper, by using Raman scattering (RS), scanning electron microscopy (SEM), and cathodoluminescence (CL) measurements, we attempt to establish a link between the optical quality and the strain relaxation in the GaNP epilayers and GaNP/GaP multiple quantum wells (MQW) structures.

2. Samples and methods

All investigated structures were grown by gas-source molecular-beam epitaxy (GS MBE) on (100) GaP substrates. Both thick GaNP epilayers (with a thickness of 0.25–0.75 μm) and 7-period GaNP/GaP (70/200 Å) MQW structures were studied. N composition in the

E-mail address: irb@ifm.liu.se (I.A. Buyanova).

alloy was determined from a simulation of a high-resolution X-ray rocking curve (XRC) data. The PL was excited by the 514 nm line of an Ar⁺ ion laser. The resulting PL emissions were dispersed using a double-grating monochromator and detected by a photomultiplier tube. The Raman scattering spectra were obtained in the backscattering geometry using the 325 nm line of a He–Cd laser in a Renishaw micro-Raman system. A Gemini Leo microscope equipped with a MONOCL Oxford Instrument attachment was used for SEM and CL measurements. The CL spectra and images were taken at 7 K with an accelerating voltage of 15 kV.

3. Experimental results and discussion

Fig. 1 shows transformation of PL spectra as a function of N content x in the GaN_xP_{1-x} alloy. A strong red shift of the PL emission with increasing x , which is clearly seen in both GaNP epilayers and GaNP/GaP MQW structures, represents a giant bowing effect in the alloy band-gap energy, consistent with previous findings [1–3]. In addition, a severe decrease in the PL intensity is observed for the GaNP epilayers with $x > 1\%$ —Fig. 1b. Since a similar increase in N content does not affect the PL intensity in the coherently strained MQW structures (Fig. 1a), this effect can be attributed to strain relaxation in the thick GaNP epilayers, degrading their structural quality.

To evaluate the biaxial strain in the thick GaNP epilayers, RS measurements were performed—see

Fig. 2a. The RS peaks related to the GaP-like longitudinal-optical (LO) phonon (labeled as LO₁) and a weak transverse-optic (TO) mode (labeled as TO₁) dominate the 350–420 cm⁻¹ spectral range. The addition of nitrogen leads to the emergence of a new RS peak, LO₂, at around 500 cm⁻¹. The LO₂ frequency is very close to that of the local mode of nitrogen in GaP at 488 cm⁻¹ [5], suggesting that it represents the Ga–N bond vibrations in the GaP matrix. The frequency of the LO₁ mode decreases almost linearly with a slope of $\approx -1.1x$ cm⁻¹ for $x < 1.5\%$ (Fig. 2b), whereas a somewhat weaker compositional dependence is observed for the higher nitrogen compositions. On the other hand, the LO₂ frequency increases at a much higher rate of approximately $+2.6$ cm⁻¹/x(%).

The observed shift of the phonon frequencies can be caused by the alloying and/or residual biaxial strain in the GaNP. Assuming Vegard's law, the strain-induced shift in the phonon frequency can be estimated using the standard method given in Ref. [6]. The obtained shift of the LO₁ frequency is $-1.13x$ cm⁻¹ and is shown in Fig. 2b by the dotted line. The close match with the data shows that the strain is the dominant cause for the observed shift of the phonon frequencies. The weaker compositional dependence of the LO₁ frequency observed for $x > 1.5\%$ indicates partial relaxation of the

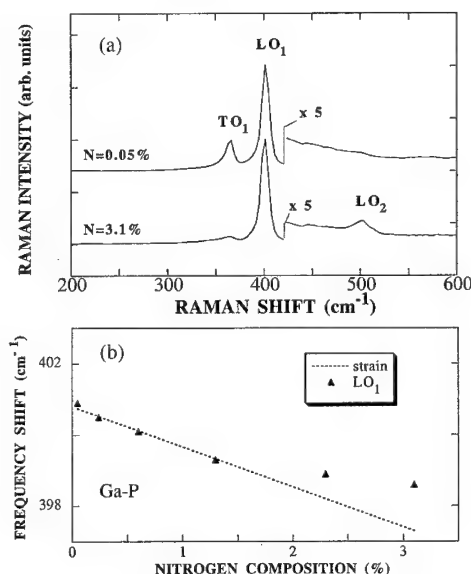

Fig. 2. (a) Room-temperature RS spectra of the GaNP epilayers with the lowest (0.05%) and highest (3.1%) N compositions studied. The spectra are normalized to the intensity of the LO₁ mode and shifted in the vertical direction, for clarity. (b) Frequency shift of the GaP-like (LO₁) phonon as a function of N content. The estimated shift of the LO₁ frequency due to the biaxial strain in the GaNP epilayer is shown by the dotted line.

Fig. 4. The SEM (a) and corresponding panchromatic CL (b) images, taken at 7 K, showing the formation of pits in the partially relaxed $\text{GaN}_{0.03}\text{P}_{0.97}$ epilayer.

residual strain in the epilayers, also confirmed by the XRC measurements.

Effect of strain relaxation on the structural quality of the GaNP alloy can be determined by using SEM and CL measurements. The pseudomorphic GaNP epilayers with low N content ($< 1\%$) and strained $\text{GaN}_x\text{P}_{1-x}/\text{GaP}$ MQW structures with x up to 4% exhibit superior crystalline quality with very low density of extended defects. On the other hand, several types of structural defects such as dislocations and/or microcracks (Fig. 3a) are observed in the partially relaxed $\text{GaN}_x\text{P}_{1-x}$ epilayers with $x \geq 1.5\%$. The strain relaxation seems to be rather inhomogeneous, since defect density varies over the sample area. Moreover, formation of pits rather than misfit dislocations is observed within certain areas of the GaNP epilayers with $x \geq 3\%$ —Fig. 4a. The overall defect density strongly increases with increasing N composition.

All the defects appear as dark areas in the CL images (Figs. 3b and 4b), indicating that the surrounding regions have a higher concentration of NR recombination centers. Some of the dislocations and pits exhibit a bright halo around the dark image. This is typical for impurity segregation at the defect core leading to a zone around defect with a reduced concentration of the NR centers and, thus, bright halo in the CL images. The CL spectra measured from the dark area around the

Fig. 5. CL spectra measured at 7 K from defect-free (solid lines) and dark line (dashed lines) areas from the GaNP epilayers with N composition of 0.9% and 3.1%.

dislocation/microcrack and defect-free area are shown in Fig. 5 by the dashed and solid lines, respectively. In addition to a severe decrease in the CL intensity, spectral position of the CL spectra, measured near the dislocation, is shifted towards higher energies. The observed shift indicates higher degree of strain relaxation around the extended defects. Thus, the non-uniformity in the biaxial strain is largely responsible for the severe broadening of the macro-PL spectra, observed in the partially relaxed structures.

4. Conclusions

We have studied the effect of strain relaxation on the optical quality of the GaNP alloy. By using the SEM and CL measurements, the decrease in radiative efficiency of the GaNP alloy with increasing N content is shown to be related to the formation of the extended structural defects. The defect formation is a result of strain relaxation in the GaNP layers, which are lattice mismatched to GaP substrate. According to the CL measurements, all extended defects act as competing, non-radiative channels, leading to the strong decrease in the radiative efficiency. From the CL mapping experiments, the non-uniformity in strain distribution around the extended defects is partly responsible for the broadening of the luminescence spectra recorded in the macro-PL experiments.

Positron annihilation in AlN and GaN

N.Yu. Arutyunov^{a,*}, V.V. Emtsev^b, A.V. Mikhailin^a, V.Yu. Davidov^b

^a *Institute of Electronics, UAS, 700170 Tashkent, Uzbekistan*

^b *Ioffe Physicotechnical Institute, RAS, 194021 St. Petersburg, Russia*

Abstract

The measurements of one-dimensional angular correlation of the annihilation radiation (1D-ACAR) have been carried out for AlN and GaN as well as for some related materials (Al, Ga, GaP, GaAs, GaSb) which have been used as samples of references the analysis of results. The numeral values of characteristic length of radius of spherical volume to be occupied by annihilating electron (r'_s) have differed significantly from the corresponding values (r_s) calculated by the conventional independent-particle-model (IPM) for ideal Fermi-gas: r'_s (AlN) $\approx 1.28 r_s$, where r_s (AlN) ≈ 1.61 a.u., and r'_s (GaN) $\approx 1.66 r_s$, where r_s (GaN) ≈ 1.64 a.u. The electron-positron “ion radii” reconstructed by the high-momentum components (HMC) of 1D-ACAR for Al^{3+} , Ga^{3+} cores as well as numeral r'_s values provide some reasons to believe that Ga- and Al-vacancies and their impurity complexes are effective centers of the positron localization in AlN and GaN; it is assumed that these complexes include V_{Ga} , V_{Al} , and N atom ($V_{\text{Ga}} - N_{\text{Ga}}$ in GaN and $V_{\text{Al}} - N_{\text{Al}}$ in AlN) where the nitrogen atom is likely to be in the configuration of substitution (anti-site), N_{Ga}^+ and N_{Al}^+ , respectively. © 2001 Elsevier Science B.V. Keywords: Positron; Annihilation; Nitrides; Defects

1. Introduction

In this work, an attempt aimed at “probing” the point defects has been undertaken by the thermalized positrons for AlN and GaN nitrides. Preliminary experiments have shown that the positron is partially localized in the area of vacancy-type point defects in these materials (roughly estimated concentration of the positron-sensitive centers has been over the range from 10^{17} to 10^{18} cm^{-3}). The annihilation radiation to be emitted out of the sample bears the information concerning the microstructure of defects; in our experiments the annihilation gamma-quanta have been detected by the measurements of the angular correlation. On the basis of the data obtained, the average electron density as well as the electron-positron “ion radius” which characterizes the ion radius of cores surrounding the positron have been estimated. The results indicate the presence of the vacancy complexes consisting of V_{Ga} ,

V_{Al} , and the atom of N in the anti-site configuration ($V_{\text{Ga}} - N_{\text{Ga}}$ in GaN and $V_{\text{Al}} - N_{\text{Al}}$ in AlN, respectively).

2. Experimental

The measurements have been conducted by the spectrometer of the angular correlations possessing the angular resolution $\sim 0.9 \text{ mrad}$ [1]; for more details about the experimental procedure see Ref. [2]. All measurements were performed at 18°C .

As AlN sample, the film (thickness $\sim 120 \mu\text{m}$) of p-type, $p \sim 10^{18} \text{ cm}^{-3}$, and as GaN sample the thick ($\sim 100 \mu\text{m}$) epitaxial film on the sapphire substrate, also of p-type, $p \sim 10^{17} \text{ cm}^{-3}$ have been used (for more details about samples, see Ref. [3]).

For a comparative analysis, experiments have been performed for metals Al and Ga as well as for a homologous pair of “perfect” single crystals GaP and GaAs related to GaN. These materials have served as the reference materials (more detailed information concerning the investigated materials of references is given in Ref. [3]).

3. The positron annihilation in AlN and GaN: the 1D-ACAR data

The 1D-ACAR spectral curves recorded for AlN and GaN are characteristic of the ion-covalent bonding in the crystal lattice (the curves are not presented here; see Fig. 1 in Ref. [3]). The estimation of the average electron density obtained on the basis of the independent particle model (IPM) for ideal electron Fermi-gas (for more details see, for instance, Ref. [4]) leads to the magnitude of the electron radius (r_s) of the sphere occupied by one electron for AlN r_s (AlN) ≈ 1.61 a.u. and r_s (GaN) ≈ 1.64 a.u., respectively. The evaluation of half-width-on-half-maximum (HWHM, or $\theta_{1/2}$) of 1D-ACAR by the simplified expression $\theta_{1/2} \approx 9.923 r_s^{-1}$ (see Ref. [4] as well as Ref. [6,10]) has given the value $\theta_{1/2}$ (AlN) ≈ 6.16 mrad for AlN, and $\theta_{1/2}$ (GaN) ≈ 6.03 mrad for GaN; on the whole, the obtained experimental data are in agreement with these magnitudes though they both proved to be less in value, $\theta_{1/2}$ (AlN, exper.) ≈ 5.85 mrad and $\theta_{1/2}$ (GaN, exper.) ≈ 4.9 mrad. This correlation between the experimental and calculated data is qualitatively different from the picture to be observed for the whole range of the materials of references (see Fig. 1).

Directly related to the electron density, the value of Fermi-momentum θ_F has been found by the value of HWHM of the momentum density distribution (see Ref. [3]): $\text{HWHM} = (6.7\text{--}6.9) \times 10^{-3} m_0 c$ and $\text{HWHM} = (4.8\text{--}5.1) \times 10^{-3} m_0 c$ for AlN and GaN. Having assumed that the enhancement of the electron density around the positron does not distort significantly its average value in AlN and GaN (as it takes place for all

wide-gap semiconductors (Ref. [5])), one may estimate the r'_s parameter for the investigated materials within the framework of the ideal Fermi-gas model. It has proven to be that for both AlN and GaN, the electron density to be obtained by means of the experimental θ_F values is markedly lower in comparison with the magnitude to be predicted on the basis of the IPM approach for ideal electron Fermi-gas, r'_s (AlN) $\approx 1.28 r_s$ and r'_s (GaN) $\approx 1.66 r_s$. These numeral values indicate the process of the annihilation of positron in the regions of defects of a vacancy-type, where the distortions of the crystal lattice result in the decrease of the average electron density. In this connection, let us now consider these regions in the light of the results obtained for the high-momentum range ($\theta > \theta_F$) of 1D-ACAR.

4. Ion cores of AlN and GaN and high-momentum component of 1D-ACAR

It is well known that the 1D-ACAR within the region $\theta > \theta_F$ bears the information concerning the chemical nature of cores as the outer shell core electron wave functions 'retain' to a great extent their atomic character (for more details see, for instance Refs. [1,4,6–10]). Within the range $0 \leq r < \kappa_F^{-1}$ (κ_F is the absolute value of the electron wave vector) the dominant contribution to the detected momentum distribution is due to the exponentially subsiding part of the outer shell core electron wave functions. The overlapping of the positron and core electron wave functions reaches a maximum at length r_m and in itself is a parameter of HMC 1D-ACAR curve (some systematic data on the parameter r_m for various materials one may find, for instance, in Refs. [7–10]). A number of studies on the ion crystal and metals [4], high- T_c superconductors [7,8], and diamond-like semiconductors [9,10] have always evidenced that $r_m \approx r_i$, where r_i is the ion radius of that core which possesses the largest volume and least positive effective charge. Below, the results obtained for GaN and AlN are compared to the data available for metals Al and Ga as well as for GaP, GaAs, and GaSb which may serve as a certain standard for determination of a chemical nature of cores whose electrons give a contribution to the electron-positron annihilation in GaN and AlN.

The HMC of 1D-ACAR curves for metals mentioned above is characterized by the values of r_m (Al^{3+}) $\approx 0.519 \pm 0.011$ Å and r_m (Ga^{3+}) $\approx 0.584 \pm 0.015$ Å, Ref. [3], which correlate well with the conventional magnitudes of ion radii: r_i (Al^{3+}) ≈ 0.53 Å and r_i (Ga^{3+}) ≈ 0.62 Å, Ref. [12]. A similar picture for HMC of 1D-ACAR has been observed for homologous consequence of GaP, GaAs, and GaSb, where the relation $r_m(\text{Ga} \langle \text{B}^5 \rangle) / r_m(\text{Ga}^{3+})$ was found to be equal to 1,0086, 1,054, and 1,11 for $\langle \text{B}^5 \rangle = \text{P, As, and Sb}$, respectively (see also Refs. [6,10]).

Fig. 1. The HWHM of 1D-ACAR ($\theta_{1/2}$) for AlN, GaN and materials of references vs. lattice constant: dots are experimental data, triangles are the results of calculations made on the basis of the model of ideal Fermi-gas of electrons [4,11]. The arrows shown here for clarity are directed from the experimental data to the calculated ones; the results for the nitrides are qualitatively different from those obtained for the materials of references (see text).

The estimated r_s values characterizing the average electron density in metals Al and Ga are r_s (Al) ≈ 2.07 a.u. and r_s (Ga) ≈ 2.19 a.u.; corresponding magnitudes of HWHM of 1D-ACAR curves are $\theta_{1/2}$ (Al) ≈ 4.8 mrad and $\theta_{1/2}$ (Ga) ≈ 4.53 mrad. These values and the experimental ones are in reasonably good agreement: $\theta_{1/2}$ (Al, exper.) ≈ 4.95 mrad and $\theta_{1/2}$ (Ga, exper.) ≈ 4.75 mrad (see Fig. 1). Let us now to apply these data on r_s and r_m values as a certain standard for a qualitative analysis of the results obtained for nitrides.

5. HMC of 1D-ACAR for AlN, GaN, and materials of references

The presence of four Ga^{3+} (or Al^{3+}) cores in the first coordination sphere of the negatively (effectively) charged nitrogen atom in the perfect crystal lattice of GaN (or AlN) creates conditions in which the outer shell core electrons of Ga^{3+} (or Al^{3+}) give a predominating contribution to the positron annihilation process in cores. If the value of r_m (Ga^{3+}) $\approx 0.584 \pm 0.015$ Å is supposed to be a standard length, then the deviation from this magnitude is less than 1% for GaP and 5% for GaAs. Indeed, as it has been established for most perfect GaP and GaAs—structurally closest materials to GaN nitride—the relations r_m (GaP)/ r_m (Ga^{3+}) and r_m (GaAs)/ r_m (Ga^{3+}) are close to unity, 1.0086 and 1.054, respectively, Ref. [10], i.e. within the accuracy of measurements the magnitude of the electron positron ‘ion radius’ r_m is determined by the 3d Ga^{3+} shell.

For the investigated nitrides, nevertheless, a somewhat different picture has been observed (see Fig. 2). Here, marked deviations of the r_m value from its standard magnitude have been revealed: the relation r_m (AlN)/ r_m (Al^{3+}) is, approximately, 1.249, and a somewhat less value 1.108 has been obtained for r_m (GaN)/ r_m (Ga^{3+}). It is important to emphasize that for GaN a similar magnitude of this relation was found when the tetrahedral structures served as standards: $\{r_m$ (GaN)/ r_m (GaP) $\} \approx 1.0986$ and $\{r_m$ (GaN)/ r_m (GaAs) $\} \approx 1.051$, i.e. again we have obtained for GaN the increase of r_m values within the interval from $\sim 5\%$ to $\sim 10\%$. Such an increase of r_m values in the investigated AlN and GaN, probably, reflects the availability of the increased distances between the cores of the nearest surroundings of positron resulting in a considerable decrease of the electron density around the positron as compared to the predicted values obtained by the IPM approach for the ideal electron Fermi-gas (see above). These two circumstances—the increase of the electron–positron ‘ion radius’ r_m in comparison with the chosen standard value and the decrease of the electron density around the positron in the crystal lattice indicate the process of annihilation of positrons trapped by vacancy-type defects, where the positron may

Fig. 2. Electron positron ‘ion radii’ (r_m) in nitrides and materials of references vs. the lattice constant: the squares indicate the deviations in magnitude of r_m from their standard values obtained for cores Al^{3+} and Ga^{3+} in corresponding metals; the circles are the same deviation of value obtained for the conventional ion radius (r_i) of B^{5-} , N^{5-} , P^{5-} , As^{5-} , and Sb^{5-} respectively (solid and dashed lines of different lengths are shown for clarity indicating the prevailing process of the annihilation of positrons in the outer shell of Al^{3+} and Ga^{3+} ion cores; the values of r_i were taken from Ref. [12]).

annihilate in the outer shells of Ga^{3+} in GaN and Al^{3+} in AlN.

Meanwhile, as is generally known, the N^{5+} -vacancies must have a repulsive potential for positron (see Ref. [5]). So, for self-consistent interpretation of the whole set of the obtained results it is required to put forward a supposition about the annihilation of positron in the region of complex, which includes Ga-vacancy in GaN and Al-vacancy in AlN. The defects of substitution N_{Ga}^+ and N_{Al}^+ (which are similar to anti-sites As_{Ga}^+ in GaAs) may be involved in the microstructure of such complexes. There are some reasons to believe that these defects, N_{Ga}^+ and N_{Al}^+ , compensate for the negative charge of Ga-vacancy or Al-vacancy. The centers consisting of the vacancies V_{Ga} or V_{Al} in which the electron density decreased and where the process of the positron annihilation occurred with outer shell core electrons of Ga^{3+} and Al^{3+} ,—such defects, may have the configuration $\text{V}_{\text{Ga}} - \text{N}_{\text{Ga}}^+$ in GaN and $\text{V}_{\text{Al}} - \text{N}_{\text{Al}}^+$ in AlN.

6. Conclusion

In this work, the results of measurements of 1D-ACAR for GaN and AlN are discussed. The radius per one electron r_s' estimated by 1D-ACAR data is higher by a factor of 1.28 and 1.66 for AlN and GaN, respectively, in comparison with the numeral values predicted within the framework of the IPM approach for ideal Fermi-gas of electrons.

The comparative analysis of systematic 1D-ACAR data for Al, Ga, GaP, GaAs, AlN, and GaN shows that the high-momentum component of 1D-ACAR is due to the annihilation of positrons in the outer shell of Ga^{3+} cores in GaN and Al^{3+} cores in AlN. Non-contradictory interpretation of the results is given on the basis of the positron annihilation in the regions of the vacancy complexes, $V_{\text{Ga}} - N_{\text{Ga}}$ in GaN and $V_{\text{Al}} - N_{\text{Al}}$ in AlN; for such defects, the nitrogen atom is likely to be in the configuration of substitution (anti-site), N_{Ga}^+ in GaN and N_{Al}^+ in AlN.

Distribution of the lateral correlation length in GaN epitaxial layers

J. Kozłowski*, R. Paszkiewicz, R. Korbutowicz, M. Tlaczala

Institute of Microsystem Technology, Wrocław University of Technology, Janiszewskiego 11/17, 50 372 Wrocław, Poland

Abstract

GaN structures belong to the most popular wide-bandgap semiconductors. Large lattice mismatch existing between the layer and substrates (3.5% for SiC and even 16% in the case of sapphire substrate) results in structures with a large number of defects. The typical GaN epitaxial layer consists of dislocation-free regions with lateral dimensions equal to a few hundred nanometers. The dislocation density changes from 10^8 cm^{-2} inside the grains to 10^{10} cm^{-2} in the grain boundaries. The average value of the lateral correlation lengths (coherence wavelength) seems to be not quite satisfactory. Particularly, it is connected with lateral direction, because the vertical length is approximately equal to the thickness of the epitaxial layer. This paper presents the new approach for the determination of GaN crystallites dislocation-free block size distributions. This method is based on the X-ray peak profile analysis and solution of the Fredholm integral equation. The necessary peaks are obtained from the high-resolution X-ray diffractometry measurements. The obtained results have been shown for the various samples: GaN layers grown on low temperature buffer layer (GaN or AlN). Very interesting results were obtained in the first case, where two different sizes of the blocks appear. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: X-ray diffraction; Lateral correlation length; GaN

1. Introduction

The GaN epitaxial layers exhibit a high density of structural defects. Dislocation densities may be up to 10^{10} cm^{-2} [1]. It is known that the columnar structure is typical for these epitaxial layers deposited on sapphire, or SiC substrate. Twist, tilt and sizes of the blocks as well as lattice strains should be controlled during the technological process. Metzger et al. [2] have been proposed some methods based on the X-ray measurements, which could be used in order to estimate some structural parameters of the GaN layers grown on *c*-plane sapphire. Especially, lateral correlation length and vertical correlation length of the GaN blocks inside the layer could be calculated.

In this paper, a new approach which allows to determine the distribution of the block sizes is proposed.

Our calculations are based on the X-ray peak profile analysis and solution of the Fredholm integral equation [3,4].

2. The model of X-ray diffraction by real crystal

The experimental X-ray diffraction line profile $h(s)$ may be treated as a convolution of the pure line profile $f(t)$ with a standard (instrumental) line profile $g(s - t)$:

$$\int_{-\sigma}^{\sigma} g(s - t) f(t) dt = h(s), \quad (1)$$

where σ is the limit of the diffraction angle for a single line.

If the layer consists of blocks of the same shape and different sizes distributed according to size distribution p , then the pure line profile is the sum of the pure line

E-mail address: janx@wtm.ite.pwr.wroc.pl (J. Kozłowski).

profiles from crystallites:

$$\int_0^N \Phi(n, s) p(n) dn = f(s), \quad (2)$$

where $\Phi(n, s)$ is the inverse Fourier transform of function autocorrelation describing the crystalline block shape of the size characterised by number n and N is a sufficiently large number (N must be so large, that $p(n) = 0$ for $n > N$).

In the small area surrounding the Bragg angle, the angular profile of X-ray from a parallel beam diffracted by the layer consists of monocrystal blocks that can be interpreted after Kojdecki [4,5], Kojdecki, Mielcarek [6,7] and Wilson [8] as

$$\int_{-\sigma}^{+\sigma} \left[\int_0^N \Phi(n, s - t) p(n) dn \right] r(t) dt = f(s) \quad (3)$$

or as

$$\int_{-\sigma}^{+\sigma} \left[\int_0^N \Psi(n, s - t) v(n) dn \right] r(t) dt = f(s), \quad (4)$$

where $p(n)$ is the number-weighted size distribution, $v(n)$ the volume-weighted size distribution ($v(n) = p(n)n^3$) and $r(s)$ the lattice strain distribution, $\Psi(n, s) = \Phi(n, s)/n^3$.

The crystallite size distribution $p(n)$ (number-weighted) or $v(n)$ (volume-weighted) can be interpreted as a density of probability of finding a crystallite of an assumed size characterised by a number n in the analysed layer. The lattice strain distribution $r(t)$ can be interpreted as a density of probability of finding the crystallite, with interplanar distance (in analysed direction) differing $-td \cot(\theta_0)$ from the averaged one ($t = \theta - \theta_0$, θ —the Bragg angle).

Formula (4), evaluated from (3) can be treated as an equation, the solution of which is a pair of functions v and r characterising the investigated sample. Both Eqs. (1) and (4) are called ill-posed problems and they can be approximately solved only by special methods, e.g. based on Tikhonov's regularisation idea [3], presented by Kojdecki [4,6].

3. Results

The proposed method of the block size and lattice strain distribution determination was applied for the GaN/GaN/sapphire and GaN/AlN/sapphire epitaxial layers. The necessary measurements of the experimental as well as instrumental line profiles have been done using a MRD-Philips X-ray diffractometer. Triple-axis optics and $\theta/2\theta$ scan mode was provided. The calculations have been done for three pairs of instrumental and experimental line profiles. GaAs substrate was used as a reference crystal and the peaks presented in Table 1 were chosen, because they have quite similar angles of the

incident and diffracted beam (similar diffraction geometry).

The samples were prepared in an atmospheric pressure, single wafer vertical flow MOVPE system. Figs. 1–3 present the results (especially, density distribution of the lateral correlation lengths) obtained for the

Fig. 3. Density of the lateral correlation length volume-weighted distribution in GaN/AlN_{buffer}/sapphire. Strain $\varepsilon = 7 \times 10^{-5}$.

three selected example layers. Sample C03 (Fig. 1) is the GaN layer deposited on the low temperature ($T \approx 800$ K) GaN buffer layer grown on the *c*-plane sapphire substrate.

Sample CE682 (Fig. 2) was grown as following: on *c*-plane sapphire substrate was deposited on a low temperature AlN buffer layer, then 2 μ m GaN layer was deposited in high temperature ($T = 1313$ K). Next, the temperature was decreased to room temperature, then it was raised to the growth value for the next deposition's step: there were two other layers deposited: GaN layer (2.63 μ m) and 30 nm of Al_{*x*}Ga_{1-*x*}N (*x* > 50%). This treatment was made for electrical measurements. The last sample E2 (Fig. 3) was GaN template on a sapphire substrate.

The lattice strain distribution $r(t)$ is obtained from formula (4), using the method described above. This is the second-order lattice strain (relative change of lattice parameter with respect to the average value). The value ε is the mean of the absolute second-order lattice strain.

In the first case (Fig. 1), two fractions of GaN grains are visible with the average lateral correlation lengths equal to 93.9 and 434.2 nm. It can be strictly connected with the double layer grown on the substrate. Sample C03 has strain $\varepsilon = 2 \times 10^{-4}$.

Sample CE682 (Fig. 2) has the small lateral correlation length of only 95.6 nm.

The sample E2 (Fig. 3) has the larger lateral correlation length of 258.8 nm.

In spite of the small correlation length sizes in sample CE682 the strain is equal to strain in sample E2

($\varepsilon = 7 \times 10^{-5}$). The grains of CE682 are very small, but temperature treatment in consequence gave a small value of strain.

4. Summary

The method, which can be used in order to obtain the structural information, is connected with the lateral correlation length distribution and additionally a lattice strain distribution in GaN layers. This is the first method of this kind. The average values of lateral correlation lengths of typical GaN structures published are in the same range as that presented in this paper. The obtained results confirm the differences between tested samples.

The proposed method seems to be very useful in the structural analysis of the non-perfect epitaxial layer.

Abstract

Several local vibrational modes (LVMs), observed in magnesium-doped high-pressure grown bulk samples, are attributed to two types of magnesium–oxygen complexes. The equivalent high-energy modes for beryllium–oxygen complexes are also observed in GaN:Be samples. Therefore, oxygen plays two roles for p-type doping of GaN: it compensates the acceptors and makes complexes with them. In addition to the well known LVM at 3125 cm^{-1} resulting from the passivation of the magnesium acceptor by hydrogen, two new modes at 4090 and 4110 cm^{-1} (at 6 K) are observed in as-grown OMVPE layers. We interpret them as originating from rotating hydrogen molecules in interstitial sites of the GaN lattice. Therefore, hydrogen passivates the acceptors and is also present in molecular form. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Acceptors; Hydrogen; Oxygen

1. Introduction

Some of the techniques of growth of gallium nitride introduce large amounts of unintentional impurities. On the one hand, undoped bulk materials grown under high pressure of nitrogen have a large electron concentration which is attributed to unintentional oxygen incorporation [1]. The same material doped with magnesium acceptors becomes either semi-insulating or slightly p-type [2,3]. The reason for this change of behaviour with magnesium doping can be (i) compensation between oxygen donors and magnesium acceptors; (ii) formation of Mg–O complexes; (iii) chemical gettering (formation of MgO precipitates). Among these possibilities, two received experimental support: UV reflectivity measurements suggested the formation of MgO precipitates [4] whereas positron annihilation experiments suggested the existence of negatively charged magnesium acceptors [5]. It must also be noted that the co-doping of GaN by both oxygen and acceptors has been suggested both experi-

mentally [6,7] and theoretically [8,9] to give rise to efficient p-type doping with high-hole mobility. In order to get further insights on these phenomena, we have investigated by local vibrational spectroscopy bulk material grown under high pressure and doped intentionally with magnesium and/or beryllium acceptors and unintentionally with oxygen.

On the other hand, as-grown magnesium-doped layers grown by organometallic vapour phase epitaxy (OMVPE) are known to contain large hydrogen concentrations coming out from the precursors. Hydrogen makes complexes with magnesium, which can be evidenced by local vibrational mode (LVM) spectroscopy [10–12]. An open question is whether it is the only role played by hydrogen in this material. In order to answer this question, we have also investigated as-grown OMVPE layers on sapphire substrates.

2. Samples and experiments

Bulk samples are grown by high-pressure synthesis method without seed. They are grown from the solution

*Corresponding author. Fax: +33-1-44-27-44-47.

E-mail address: bec@ccr.jussieu.fr (B. Clerjaud).

of nitrogen in liquid gallium under high pressures (≈ 1.5 GPa) at temperatures around 1500°C . Doping is achieved by adding 0.1–0.5% of magnesium or beryllium to the liquid gallium. The crystals we have investigated have a typical thickness around $300\ \mu\text{m}$ and lateral dimensions about 2 mm. They are of wurtzite structure with the c -axis perpendicular to the platelet.

Magnesium-doped epitaxial layers are grown by OMVPE at about 1000°C on sapphire substrates. They are of wurtzite structure with the c -axis perpendicular to the layer. Mg acceptor concentration exceeds 10^{19} cm^{-3} . As-grown samples are insulating at room temperature.

Infrared experiments have been performed with Bomem DA3+ or DA8 interferometers equipped with CaF_2 , KBr or mylar beam-splitters and cooled InSb, HgCdTe detectors or silicon bolometer. The samples can be cooled down to liquid helium temperature using Oxford Instruments CF 204 or CF 1204 cryostats.

Epitaxial layers have been investigated using the multitransmission set-up described in Ref. [12]. Bulk materials have been investigated with the wave vector of the light parallel to the c -axis.

3. Magnesium-doped bulk samples

In magnesium-doped bulk samples, in addition to the lattice absorption, two intense absorptions at 395.6 and 781.8 cm^{-1} , shown in Figs. 1 and 2, exist. They are observable at elevated temperature and, therefore, can be assigned to LVMs. The full widths at half maxima are 2 cm^{-1} for the 396 cm^{-1} mode and 2.5 cm^{-1} for the 782 cm^{-1} mode. The wave number of the high-energy mode being slightly lower than twice the low-energy mode, one can suspect the high-energy mode to be an

Fig. 1. Absorption spectrum of the magnesium-oxygen complex in the 400 cm^{-1} range at $T = 6\text{ K}$. The upper trace is the experimental spectrum while the lower one is a simulation.

Fig. 2. Absorption spectrum of the magnesium-oxygen complex in the 800 cm^{-1} range at $T = 6\text{ K}$. The upper trace is the experimental spectrum while the lower one is a simulation.

overtone of the low-energy one. However, this possibility seems to be very unlikely as the intensity of the 782 cm^{-1} mode is twice larger than the 396 cm^{-1} mode. We believe that these modes are magnesium related. One of the reasons for this assignment is that they are not observed in beryllium-doped samples. Another one is that at energies lower than that of each main peak, two smaller ones are observed with intensities about 13% of the main peaks; they can be due to the ^{25}Mg and ^{26}Mg isotopes whose natural abundances are 10% and 11%, respectively, as it can be seen on the simulations shown in the lower traces of Figs. 1 and 2. In order to simulate the true absorption spectra, one needs to introduce a second set of lines consisting of ^{24}Mg related lines at 399 and 784.9 cm^{-1} and their ^{25}Mg and ^{26}Mg partners. In both spectra, the integrated intensity of the second set of lines is $1/4$ of the main set one. We assign these two sets of lines to two types of centres.

These LVMs are not due to "isolated" magnesium in substitution to gallium as they are already known from Raman spectroscopy [13–15] and do not fit to the observed wave numbers. Therefore, these LVMS are due to complexes involving magnesium. The most likely partner of magnesium is oxygen for the following reasons: (i) oxygen is the most important unintentional impurity in the samples we have investigated; (ii) the affinity of oxygen for magnesium is well known; (iii) the wave-number of the high-energy mode is in the range of the LO phonon in MgO (725 cm^{-1}). Therefore, we assign the two groups of LVMs to magnesium-oxygen complexes. It has to be emphasised that we do not have any direct proof of the involvement of oxygen in the complex; in particular, we could not find any evidence of LVMs related with ^{18}O as the natural abundance of ^{18}O is too low (0.2%) for allowing their observation in our experiments.

Fig. 3. Absorption spectrum of the beryllium-oxygen complex at $T = 6$ K.

4. Beryllium-doped bulk samples

The beryllium-doped bulk materials we have investigated are insulating at room temperature. In addition to the lattice absorption and to LVMs due to beryllium in substitution to gallium, one observes two modes at 1055 and 1063 cm^{-1} , which are shown in Fig. 3. For the same reasons as those developed in the previous section, we assign them to complexes involving beryllium and oxygen.

Bulk samples co-doped with magnesium and beryllium have also been investigated. One observes in them both the magnesium-oxygen complexes discussed in the previous section and beryllium-oxygen ones discussed in this section. This suggests that the acceptor-oxygen complexes contain only one acceptor atom.

5. Discussion on the acceptor-oxygen complexes

The main factor for determining the wave-number of a complex is the mass effect as the force constants do not depend so much of the bonds and occur at the power $1/2$. In this respect, if one considers an acceptor-oxygen bond, it is pertinent to compare its stretching LVM wave number with $f(m_A) = (1/m_A + 1/m_O)^{1/2}$ where m_A and m_O are the acceptor and oxygen masses, respectively. One can notice that the ratio of the high-energy modes wave numbers of the magnesium-oxygen and beryllium-oxygen complexes matches the $f(m_{\text{Be}})/f(m_{\text{Mg}})$ ratio.

We shall now discuss the structure of the acceptor-oxygen complexes. The simplest one can think of consists of oxygen in substitution to a nitrogen atom nearest neighbour to the acceptor in substitution to gallium (Fig. 4a). Such a complex ($\text{O}_\text{N}-\text{Mg}_{\text{Ga}}$ or $\text{O}_\text{N}-$

Fig. 4. Schematic representation of: (a) the $\text{A}-\text{O}$ complex; (b) the $(\text{A}_{\text{Ga}}-\text{O}-\text{Ga}, \text{V}_\text{N})$ defect. The “cubes” are there only for helping the perspective vision.

Be_{Ga}) has been considered by *ab-initio* calculations in the cubic phase of GaN [16] and it comes out that this defect is energetically favourable and has no level within the band gap. It seems quite likely that in wurtzite type GaN and in the case of replacement of magnesium by beryllium, one should reach the same conclusions. In the framework of this model, the modes at high energy would be assigned to the stretching modes and the modes around 396 cm^{-1} observed in Mg-doped samples to the transverse modes of the $\text{Mg}-\text{O}$ complexes. It is not clear why two types of complexes could be observed in the framework of such a model. One could think of two different geometries of the complexes: one with the acceptor-oxygen bond aligned along the c -axis and the other one in which this bond would be aligned along the other possible directions. However, this would not be compatible with our measurements as our experimental arrangement does not allow for the observation of the stretching vibrations of bonds aligned along the c -axis.

We believe that another type of complex is worth being considered: the $(\text{A}_{\text{Ga}}-\text{O}-\text{Ga}, \text{V}_\text{N})$ defect where A_{Ga} stands for the acceptor in substitution for gallium and V_N for the nitrogen vacancy. This defect, which is shown schematically in Fig. 4b, is an extension of the $(\text{Ga}-\text{O}-\text{Ga}, \text{V}_{\text{As}})$ complex observed in GaAs [17,18]; in fact, it can be considered as the same type of defect as the one discussed in the previous paragraph in which oxygen has relaxed in an off-centre position. Such a defect should be electrically active. In the framework of such a model, stretching vibrations of this complex should give rise to two modes corresponding to the modes at 782 cm^{-1} and to the one at 396 cm^{-1} in the case of magnesium doping. A splitting due to the two different gallium isotopes should exist. However, it should be small ($\leq 1 \text{ cm}^{-1}$) and not observable with the experimental line widths measured. In the framework of such a defect, several possibilities exist for explaining the occurrence of two types of complexes: (i) different charge states of the same complex; (ii) same charge state of non-equivalent complexes due to the wurtzite structure.

Fig. 5. Absorption spectrum of the H_2 molecule in GaN at $T = 6\text{ K}$.

6. Magnesium-doped OMVPE layers

As-grown samples are insulating at room temperature. In addition to the LVM at 3125 cm^{-1} due to magnesium–hydrogen complexes, two lines, shown in Fig. 5, at 4090 and 4110 cm^{-1} are observed at 6 K ; their line widths are about 10 cm^{-1} . They are due to local modes of vibration as they are still observed at room temperature slightly shifted (4087 and 4107 cm^{-1}). It has to be noted that no modes are observed around 2100 cm^{-1} , which means that these modes are not overtones. As hydrogen is known to be present in large quantities in these samples, the most likely candidate for such high-wave number modes is the hydrogen molecule. The wave number of the hydrogen molecule vibration in the lowest energy interstitial site of cubic GaN has been calculated to be 3847 cm^{-1} in the harmonic approximation and 3548 cm^{-1} taking into account anharmonic corrections [19]. It has to be noted that these calculations systematically underestimate the wave numbers even for the free hydrogen molecule. In the case of wurtzite type GaN, it has been calculated that the H_2 formation energy is lower than in cubic GaN [20], but, to our knowledge, no values for the LVM of the molecule has been published. Nevertheless, it seems that the modes we are observing are in the range expected for hydrogen molecules in GaN. Therefore, we assign these two modes to hydrogen molecules.

7. Discussion on the hydrogen molecule

The samples investigated are insulating. As it has been calculated that in insulating wurtzite type GaN, the most stable state of hydrogen is H_2 molecule at the centre of a trigonal channel [20], the experimental

observation of H_2 in insulating GaN is consistent with theory. The free hydrogen molecule is infrared inactive; in a noncentro-symmetric crystal field, the infrared transition becomes allowed. It has been pointed out that in wurtzite type GaN, a polarisation of the molecule occurs [20], which reinforces its “effective charge”.

In a free H_2 molecule, the Raman spectrum consists of two lines split by 5.9 cm^{-1} (ortho-para splitting). This is due to the coupling of the vibrational and the rotational motions of the free molecule via the anharmonicity of the molecule potential [21]. In the case of the H_2 molecule in GaAs, this splitting is 8.2 cm^{-1} [22]. When the molecule is in a crystal, it suffers the crystal potential in addition to the molecule potential; this will increase anharmonicity. For an interstitial molecule, the smaller the “cage” in which the molecule is enclosed, the larger the anharmonicity. Because of the smaller values of the GaN lattice parameters, the size of the “cage” in which the molecule is enclosed will be smaller than in GaAs and therefore, the ortho-para splitting will be larger in GaN than in GaAs. We attribute the two modes observed to rotating H_2 molecules, the low-energy mode being due to ortho-hydrogen and the high-energy mode to para-hydrogen. The 20 cm^{-1} ortho-para splitting observed reflects the small size of the channel in which the molecule is rotating. In the framework of this model, the intensity ratio between the ortho- and para-hydrogen transitions should be equal to the ratio of the degeneracies of the ground states of ortho- and para-hydrogen, i.e. 3 [22]; this is fully compatible with the experimental spectra.

It is to be noted that hydrogen-dependent lattice dilatation in epitaxial GaN films has been reported [23]. The interstitial H_2 molecules evidenced here might be responsible for this effect.

8. Conclusion

We have shown that in addition to its donor role, oxygen also makes complexes with the magnesium and beryllium acceptors. It is not yet clear whether these complexes are electrically active or not. In this respect, it is of importance to work out whether the two types of modes reported here could be due to two different charge states of the complex; experiments under illumination of the samples should be performed in order to give insight on the answer to this question.

It is now well known that hydrogen makes complexes with magnesium acceptors and passivates them. We have tried to diffuse hydrogen in beryllium-doped bulk materials in order to evidence complexes of beryllium with hydrogen; up to now we failed in observing these complexes.

We have evidenced H_2 molecules rotating in interstitial sites of the GaN lattice; the large ortho-para

splitting reflects the smallness of the “cage” in which the molecule is enclosed. The next step should be to investigate samples containing both hydrogen and deuterium in order to investigate H–D and D₂ molecules.

Note added in proof

The stretching mode wave number of the hydrogen molecule in wurtzite type GaN, calculated in the harmonic approximation, is 4235 cm^{-1} [24]; the inclusion of anharmonic corrections should lower this value.

Acknowledgements

We are very grateful to Michelle Jacquet and Nicole Lenain for the preparation of the samples for multi-transmission experiments and Christopher Latham for helpful discussions on the acceptor–oxygen complexes. T.S., E.L.-S., M.B. and I.G. acknowledge partial support from the Grant of the European Commission “Centre of Excellence”.

Abstract

Several H-vibrational lines with frequencies between 3050 and 3250 cm⁻¹ have been observed in as-grown layers of GaN grown by hydride vapor phase epitaxy. H⁺ and D⁺ were also implanted into GaN samples with a range of energies up to 11 MeV. The implants gave rise to the same lines seen in the as-grown samples and a number of new lines in addition to those seen previously. A vibrational line at 2208 cm⁻¹ was produced by both H⁺ and D⁺ implantation and is assigned to a strongly bonded molecular complex. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; H; Vibrational modes; Implantation

Hydrogen is well known to interact with the dangling bonds of native vacancy and interstitial defects in semiconductors. While hydrogenated native defects are sometimes found in as-grown crystals [1–4], a convenient method to produce these defects for study is by the implantation of H⁺ (or D⁺) [1,2,5,6]. In this paper, we report the observation of several H-vibrational lines in thick, as-grown crystals of GaN grown by hydride vapor phase epitaxy (HVPE). H⁺ and D⁺ were also implanted into HVPE GaN to produce hydrogenated lattice defects for our studies. These data provide insight into the origin and properties of the vibrational lines found in the HVPE GaN crystals.

Van de Walle proposed that H will interact with the N and Ga vacancies, V_N and V_{Ga}, in GaN and calculated the properties of the vacancy-H complexes [7]. For V_{Ga}, it was predicted that from one to four H atoms can terminate the N-dangling bonds of the defect. The H- and D-vibrational lines produced by the implantation of H⁺ and D⁺ into GaN have also been studied. Weinstein et al. discovered five H-vibrational lines between 3000 and 3150 cm⁻¹ in thin (≈4 μm) GaN epilayers that had been implanted with H⁺ and annealed near 450 °C [8].

Seager et al. discovered two lines at 3183 and 3219 cm⁻¹ in thin GaN layers that had been implanted with high doses of H⁺ (1–5 × 10¹⁷ cm⁻²) and annealed at T ≥ 600 °C [9].

Here we take advantage of the availability of thick GaN samples grown by HVPE for new studies of the hydrogenated lattice defects. H-containing defects present in the as-grown crystals can be sensitively detected. Further, the thick GaN samples can be implanted with a smaller local concentration of H or D compared to the thin layers studied previously, but with a greater total dose distributed over the thickness of the sample, giving stronger absorption lines with narrower widths.

The GaN samples used for our experiments were high quality, ≈400 μm thick, GaN single-crystal platelets grown at NEC by HVPE using a facet-initiated epitaxial overgrowth technique on GaN-nucleated sapphire substrates which were subsequently removed [10]. The dislocation density was typically 10⁷ cm⁻² and the unintentional n-type doping density was N_D ≈ 10¹⁷ cm⁻³. H⁺ and D⁺ were implanted at multiple energies through a 0.2 mm thick Al foil into the GaN. For H⁺, for example, 27 different energies between 5 and 7.6 MeV were used with a total dose of 4 × 10¹⁶ cm⁻², to produce a nearly uniform concentration of [H] = 3.6 × 10¹⁸ cm⁻³ in a layer 110 μm thick. For

one sample, H^+ and D^+ implantation energies and doses were selected to produce overlapping profiles of H and D, each with a concentration of $3.6 \times 10^{18} \text{ cm}^{-3}$ throughout a layer $110 \mu\text{m}$ thick. Samples were annealed in flowing N_2 . IR absorption spectra were measured at near 4 K, with resolution 0.5 cm^{-1} , with a Bomem DA.3 Fourier transform spectrometer. The spectra typically had oscillating baselines with a period of a few hundred wavenumbers that were subtracted.

An IR absorption spectrum, measured for a GaN sample grown by HVPE, is shown in Fig. 1, spectrum (a), and reveals five vibrational lines in the H-stretching range for the as-grown crystal. Other GaN crystals grown by HVPE showed similar H-vibrational lines. To explore the origin of these vibrational lines, HVPE GaN samples were implanted with H^+ or D^+ and then annealed at successively higher temperatures. Figs. 1 and 2 show spectra measured for the H- and D-stretching ranges, respectively. The frequencies of the vibrational lines are listed in Table 1. For annealing temperatures from 100°C to 550°C the lines seen previously in H^+ - or D^+ -implanted GaN by Weinstein et al. [8] emerged and sharpened, dominating the spectra. These H- and D-stretching lines are marked with a '*' in Figs. 1 and 2 and in Table 1.

For annealing temperatures of 600°C and above, the lines seen previously by Weinstein et al. decreased in intensity while a number of other vibrational lines with higher frequencies grew in strength. Several of these lines remained stable for annealing temperatures up to 900°C . The two H-stretching lines at 3188 and 3221 cm^{-1} (4 K)

Fig. 2. Vibrational spectra (4 K) of HVPE GaN. Spectra (a)–(c) were measured for a sample that was implanted with D^+ and annealed isochronally (30 min) in $\approx 50^\circ\text{C}$ steps. Spectrum (d) was measured for a sample that had been implanted with overlapping profiles of H^+ and D^+ and isochronally annealed up to 750°C . Spectrum (e) was measured for the same H^+ -implanted sample whose spectra are shown in Fig. 1.

have frequencies similar to the lines at 3183 and 3219 cm^{-1} (300 K) that were reported previously by Seager et al. [9]. A comparison of the spectra measured for an as-grown sample [Fig. 1, spectrum (a)] with a sample that was implanted with H^+ and annealed at 750°C [Fig. 1, spectrum (d)] shows that H^+ implantation produces the same vibrational lines that were seen in the as-grown samples. The H-stretching lines that were seen in the as-grown samples and the corresponding D lines are marked with a '+' in Figs. 1 and 2 and in Table 1.

Several additional lines are also present and are most apparent in Fig. 2 that shows the D-stretching range. The frequencies of the three sharp lines between 2332 and 2351 cm^{-1} seen in spectra (b) and (c), and the frequencies of the corresponding H-stretching lines, are given in Table 1. In spectra (a) and (b), a line at 2208 cm^{-1} is seen that has no corresponding, isotopically shifted line in the H-stretching region of the spectrum.

Weinstein et al. assigned the H-stretching lines they found in GaN that had been implanted with H^+ and annealed at $\approx 450^\circ\text{C}$ to N–H bonds and suggested that these lines were due to V_{Ga} defects, created by the implantation, whose N-dangling bonds were terminated by different numbers of H atoms [8]. This assignment was based upon the calculations of the vibrational frequencies of $V_{Ga}H_n$ defects made by Van de Walle [7]

Fig. 1. Vibrational spectra (4 K) of HVPE GaN. Spectrum (a) is for an as-grown sample. Spectra (b)–(d) were measured following anneals at the temperatures shown for a sample that was implanted with H^+ and annealed isochronally (30 min) in $\approx 50^\circ\text{C}$ steps.

(3100 cm⁻¹ for V_{Ga}H and 3470 cm⁻¹ for V_{Ga}H₄) and also upon the ratio $\omega_{\text{H}}/\omega_{\text{D}}$ for the corresponding H and D modes which was found to be typical of N–H bonds (≈ 1.34). Seager et al. also assigned the lines at 3183 and 3219 cm⁻¹, seen for GaN that had been implanted with H⁺ and annealed with $T \geq 600^\circ\text{C}$, to N–H bonds, but in this case, it was suggested that the H was bonded to the walls of cavities created by the implant and annealing cycle [9]. The ratio $\omega_{\text{H}}/\omega_{\text{D}}$ is given in Table 1 for the H- and D-stretching lines reported here and is close to 1.34, suggesting that all the H-vibrational lines are due to the stretching vibrations of N–H bonds, in agreement with the previous conclusions [8,9]. (We note that it is not possible to differentiate between H bonded to N or to another light atom, for example O, because both the vibrational frequency and value of $\omega_{\text{H}}/\omega_{\text{D}}$ would be similar.)

To further probe the rich spectrum of lines produced in GaN by H⁺ implantation, a sample was implanted with overlapping profiles of H⁺ and D⁺, and annealed at successively higher temperatures. A comparison of the vibrational spectra produced by the implantation of D⁺ alone and by overlapping profiles of H⁺ and D⁺, followed by an anneal at 750°C, is shown in Fig. 2, spectra (c) and (d), respectively. The presence of H and D in the GaN sample gives rise to a number of additional new D-stretching lines. (Corresponding new H lines were also seen in this sample.) This result shows that the vibrational lines that appear following an anneal with $T \geq 600^\circ\text{C}$ are due to multihydrogen complexes because these complexes give rise to new

lines when they contain combinations of both H and D. Other lines seen in the spectra did not show resolvable splittings.

Our results suggest that H⁺ implantation followed by annealing at temperatures with $T < 600^\circ\text{C}$ favors the formation of complexes that contain single (or at least fewer) H atoms. Annealing at higher temperatures favors the formation of complexes with multiple H atoms and higher vibrational frequencies. The presence of the vibrational lines shown in Fig. 1 in as-grown GaN samples, and for the reduced local H concentrations examined here, supports their assignment to H trapped at point defects rather than at the walls of cavities as was suggested by Seager et al. [9]. Therefore, we suggest that the defects responsible for the H- and D-vibrational lines seen in H⁺- and D⁺-implanted GaN are V_{Ga} or multi-V_{Ga} complexes, possibly trapped at impurity sites in some cases, whose N-dangling bonds are terminated by different numbers of H atoms. The vibrational lines seen in the as-grown GaN crystals have the same frequencies as the vibrational lines of the multihydrogen complexes seen for the later stages of isochronal annealing of the H⁺-implanted samples, consistent with their presence following crystal growth.

The vibrational line at 2208 cm⁻¹ is produced by the implantation of D⁺ into GaN [spectra (a) and (b) in Fig. 2] and was previously assigned to a D-stretching mode [8]. For the H⁺- and D⁺-implanted GaN samples studied here, it is clear that there is no isotopically shifted partner that corresponds to the 2208 cm⁻¹ line. Further, the 2208 cm⁻¹ line is also produced by the implantation of H⁺ into the samples [spectrum (e) in Fig. 2]. Therefore, the 2208 cm⁻¹ line cannot be due to a D-stretching mode! A recent example of another defect with a high vibrational frequency is a C–C pair that has been seen near 1800 cm⁻¹ in GaAs by Raman spectroscopy [11]. Here, we suggest that the 2208 cm⁻¹ line is also due to a complex of light, strongly bonded atoms, with the obvious possibilities being N, O, and C. (An N₂ molecule with sufficiently low symmetry in the wurtzite lattice to be IR active is an interesting possibility.) The presence of a strong 2208 cm⁻¹ line in the sample implanted with H⁺ and D⁺ [Fig. 2, spectrum (d)] is consistent with both implantations contributing to its intensity.

Clerjaud et al. have discussed the possibility that there can be defects in GaN with their transition moments along the *c*-axis of the sample [12]. In our measurements, a sample was turned to a 60° angle with respect to the viewing direction to produce a component of the polarization of the exciting light along the *c*-direction. Three new lines at frequencies of 2362, 2368, and 2403 cm⁻¹ were observed in the sample implanted with D⁺ when it was rotated away from normal incidence and, therefore, must be due to defects with their transition moments along the *c* direction.

We thank G.D. Watkins and B. Clerjaud for helpful discussions. The work at L.U. was supported by ONR Award No. N00014-94-1-0117 and NSF Grant No. DMR-9801843.

Properties of carbon as an acceptor in cubic GaN

U. Köhler*, M. Lübbbers, J. Mimkes, D.J. As

Universität Paderborn, FB6 — Physik, Warburger Str. 100, 33098 Paderborn, Germany

Abstract

Cubic gallium nitride epilayers were successfully doped with carbon using an e-beam evaporation source. Room temperature Hall measurements revealed hole concentrations up to $6 \times 10^{17} \text{ cm}^{-3}$ and hole mobilities of $200 \text{ cm}^2/\text{Vs}$. Low temperature (2 K) photoluminescence showed a donor–acceptor transition at 3.08 eV, which could clearly be assigned to the incorporation of a carbon acceptor. Thermal activation measurements were performed. They exhibited an activation energy of $E_A = 215 \text{ meV}$ both in photoluminescence and electrical measurements, respectively. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: GaN; Carbon; Acceptor; Doping

1. Introduction

Gallium nitride (GaN) and GaN-based ternaries are semiconductors currently in the focus of both scientific and industrial research. Due to their large band gap they are well-suited for a wide range of applications, e.g. as light emitters in the green to ultraviolet range or as photodetectors, especially so for solar-blind sensors. The perspective of the use as sensors is even more attractive considering the mechanical hardness and chemical stability that make GaN appear extremely attractive for potential devices operating at high temperatures or under adverse conditions [1,2].

GaN possesses two known crystal phases, wurtzite and cubic. The latter is the metastable phase, so most of the progress that has been made has been reported for hexagonal phase material [3]. However, cubic GaN (c-GaN) is predicted to have many advantages due to its higher crystal symmetry, for example higher carrier mobility because of a smaller scattering coefficient and lower effective mass [4]. Readily available, high-quality cubic material such as GaAs—which may be doped and sport a backside contact—can be used as substrate.

Cleavage facets may easily be used as laser cavity mirrors.

For optoelectronic devices, controlled doping is essential. P-type doping of GaN poses, in contrast to n-type, a serious challenge. Up to now magnesium is the p-type dopant of choice for both hexagonal and cubic GaN. However, several disadvantages of Mg present a challenge, so the usually reported room temperature free hole concentration is in the upper range of 10^{17} cm^{-3} . In metalorganic vapor phase epitaxy (MOVPE) grown GaN, the Magnesium acceptor needs an extra thermal activation. Mg is rather volatile and substitutes Ga. Therefore, doping with Mg necessitates a low growth temperature and N rich conditions, which are disadvantageous for the growth of high-quality epitaxial layers [5,6]. Due to a large acceptor ionization energy, only about 5% of the incorporated Mg atoms are electrically active at room temperature. This problem is exacerbated by its tendency for self-compensation [7,8].

Carbon presents a viable alternative to magnesium as acceptor, when substituting nitrogen [9,10]. Due to its similar atomic radius, it is easily incorporated onto an N lattice site. In previous reports, carbon doping of hexagonal gallium nitride (h-GaN) led to semi-insulating properties or to a reduction of background electron concentration [11,12]. Cubic GaN with $p = 3 \times 10^{17} \text{ cm}^{-3}$ was reported, albeit with an extremely

E-mail address: koehler@physik.uni-paderborn.de (U. Köhler).

reduced growth rate due to chlorine-induced back-etching from CCl_4 used for doping [13].

2. Experimental

Cubic gallium nitride was grown by means of rf plasma-assisted molecular beam epitaxy (MBE). Growth details are published elsewhere [6]. Molecular nitrogen was used for N supply. The substrates were semi-insulating GaAs(001). Carbon doping was accomplished by electron beam evaporation of a graphite rod and adjusting the applied power. The carbon flux was calibrated by growing C-doped gallium arsenide, assuming a similar sticking coefficient of C on GaAs and GaN. Comparison of the Hall values of hole concentration and mobility of the GaAs:C samples with literature allowed an estimate of carbon concentration and compensation in our GaAs:C layers [15]. As a result of this calculation, a carbon incorporation of $2 \times 10^{20} \text{ cm}^{-3}$ should possibly be achieved in GaN. This was confirmed with secondary ion mass spectroscopy (SIMS), where indeed a carbon concentration of $2 \times 10^{20} \text{ cm}^{-3}$ was measured.

Photoluminescence measurements were conducted between 2 K and room temperature in a He bath cryostat. A cw HeCd laser (325 nm) was used for excitation. Neutral density filters allowed a variation of the excitation power over four orders of magnitude. Spectra were recorded with a resolution of 0.2 nm. Hall effect measurements were performed in van der Pauw geometry between 77 and 420 K. The magnetic field measured 0.8 T, the samples were not illuminated during the experiment.

3. Results and discussion

The variation of the carbon influx has a profound influence on the photoluminescence spectra, as can readily be seen in Fig. 1. For moderate carbon concentrations, a PL band at $E = 3.08 \text{ eV}$ appears in spectra recorded at $T = 2 \text{ K}$. This transition is distinctly different from the well-known lines (D, X) that can also be seen at 3.27 eV and (D^0, A^0) at 3.16 eV [14]. As a more detailed analysis of this peak shows, this actually is a convolution of two separate luminescence lines separated by 25 meV at low temperatures. When increasing the temperature, the low-energy contribution thermalizes so that only the high-energy PL transition can be observed for temperatures exceeding 100 K . Therefore, it seems appropriate to attribute the lower line to a donor–acceptor recombination $(\text{D}^0, \text{A}^0)_\text{C}$, while the other is caused by a C-related band–acceptor transition, $(\text{e}, \text{A}^0)_\text{C}$. These two transition lines were fitted with Gaussians. The respective energetic positions

Fig. 2. Observed temperature shift of near-band edge PL transitions (squares: excitonic transition; diamonds: C-related band–acceptor transition, $(\text{e}, \text{A}^0)_\text{C}$; triangles: C-related donor–acceptor transition, $(\text{D}^0, \text{A}^0)_\text{C}$). The top curve denotes the gap energy as function of temperature, the lower curves are calculated for $(\text{e}, \text{A}^0)_\text{C}$ and $(\text{D}^0, \text{A}^0)_\text{C}$ transitions, respectively, using donor and acceptor energies of $E_\text{D} = 25 \text{ meV}$ and $E_\text{A} = 215 \text{ meV}$.

as a function of temperature are shown in Fig. 2. The analysis yielded an acceptor activation energy of $E_\text{A} = 215 \text{ meV}$, 15 meV below that of the Mg acceptor in c-GaN [16]. It is also below the known values for hexagonal GaN:C [7]. The full curves denote the calculated transitions as detailed, including a donor energy of 25 meV . This is the same ubiquitous donor which is also observed in undoped samples [14]. The variation of the gap energy, as lined out in the topmost curve, follows Ref. [17].

Fig. 3. Room temperature Hall effect hole concentration (dots) and low temperature PL intensity of C-related donor–acceptor transition (squares) as function of carbon flux. The lines (solid line: hole concentrations, dashed line: PL intensity) are guides to the eye.

The carbon-related transition increases steadily with carbon incorporation. As is visible in Fig. 3, the same is true for hole concentrations up to a certain saturation value, $6 \times 10^{17} \text{ cm}^{-3}$. At the same time, the room temperature Hall mobility of the holes is as high as $200 \text{ cm}^2/\text{Vs}$. Variable-temperature Hall effect measurements (not shown here) gave a thermal activation energy $E_A = 215 \text{ meV}$ of the carbon acceptor, which is in excellent agreement with the optical values. At higher carbon fluxes, however, Fig. 3 shows a drastic reduction in free hole concentration, indicative of the formation of additional compensating centers. The nature of this compensating mechanism remains unknown. Kaufmann et al. reported a similar phenomenon for magnesium doped MOVPE GaN layers with a maximum hole concentration of $6 \times 10^{17} \text{ cm}^{-3}$, albeit with mobilities $< 20 \text{ cm}^2/\text{Vs}$ [8]. They developed a model which involves self-compensation via the formation of MgV_N pairs. For GaN:C, it is tempting to assume an analogy from GaAs:C. In this system, it has been found that at high doping concentrations a compensating dicarbon complex forms [18]. This complex involves a split interstitial, i.e., one carbon atom on an As lattice site and another atom shifted along the [100] direction [19], and acts as a double donor in GaAs. An explanation along these lines might also account for a second interesting observation in Fig. 3: while the Hall effect free hole concentration decreases, there is still an increase in photoluminescence intensity of the carbon-related DAP transition, up to a tenfold higher carbon flux. Even this apparent decrease has to be looked upon with caution. For high carbon concentrations, a broad luminescence band evolves around 2.1 eV, and near-gap luminescence is quenched. Therefore, it is more helpful to consider the ratio of the

Fig. 4. Ratio of C-related donor–acceptor transition (3.08 eV) and prominent DAP transition (3.15 eV) observed in photoluminescence at $T = 2 \text{ K}$ as function of carbon incorporation.

Fig. 5. Photoluminescence intensity of GaN:C with an estimated carbon density of 10^{19} cm^{-3} as function of excitation intensity. Diamonds, dots and triangles denote the near-band edge luminescence, the squares mark the deep luminescence.

$(\text{D}^0, \text{A}^0)_\text{C}$ emission to the other near-gap lines. The result is depicted in Fig. 4. It can be clearly seen as to how carbon acceptors are incorporated up to the highest experimentally available fluxes. More detailed calculations with respect of formation rate, activation energies and net doping effect need to be performed. Raman measurements will be employed in order to clarify the nature of this complex.

The existence of such a deep donor carbon complex may well be the cause of the deep luminescence observable in highly doped GaN layers (cf. Fig. 1). This donor would lie in the gap ca. 1.15 eV below the conduction band. Photoluminescence measurements carried out with varying excitation intensity at

$T = 2$ K clearly show the localized character of this red luminescence, as can be seen in the different exponent k in Fig. 5. The near-gap luminescence (denoted by diamonds, triangles and dots, respectively) can be described with a power law $I \sim L^{1.2}$, in agreement with the literature [20]. In contrast, the deep luminescence, marked by squares, follows $I \sim L^{0.95}$, as would be expected from a localized defect.

4. Conclusions

Successful p-type doping of MBE grown cubic gallium nitride epilayers has been demonstrated. Room temperature Hall effect measurements show hole concentrations up to $6 \times 10^{17} \text{ cm}^{-3}$ and hole mobilities of $200 \text{ cm}^2/\text{Vs}$. Photoluminescence showed a carbon-related transition at $E = 3.08 \text{ eV}$. With the help of temperature-dependent analysis, this line could be ascribed to a donor–acceptor transition with an activation energy $E_A = 215 \text{ meV}$. This is less than the previously reported magnesium activation energy and in excellent agreement with variable-temperature Hall measurements. At high carbon concentrations, near-edge luminescence quenching due to the formation of a deep level is observed. This deep defect lies 1.15 eV below the conduction band.

Electrically active defects in AlGa_xN alloys grown by metalorganic chemical vapor deposition

D. Seghier*, H.P. Gislason

Science Institute, University of Iceland, Dunhagi 3, IS-107 Reykjavik, Iceland

Abstract

We investigated two series of metalorganic chemical-vapor-deposition-grown Al_xGa_{1-x}N samples with Al compositions $x = 0.1$ and 0.3 and free electron concentrations 2.4×10^{17} and $5.2 \times 10^{17} \text{ cm}^{-3}$, respectively. Shallow and deep centers were investigated using electrical characterization methods. Capacitance vs. temperature measurements show the presence of a dominant donor level with a binding energy of about 118 meV in the sample with $x = 0.1$ and 90 meV in the sample with $x = 0.3$. Moreover, we observe a hysteresis in the capacitance–voltage measurements from the sample with higher x . Deep-level transient spectroscopy measurements show that this long time relaxation phenomenon is caused by the presence of interface defects between Au and the AlGa_xN layer, which become more significant with increase in x . The high Al mole fraction creates potential fluctuations at the surface of the sample and makes the surface behave as an interfacial layer. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: AlGa_xN; Defects; Conductivity; Metalorganic chemical-vapor-deposition-grown

1. Introduction

GaN and its ternary solution with AlN are of great interest for applications in optoelectronics and high-temperature/high-power/high-frequency electronics [1,2]. When undoped, AlGa_xN layers tended to be n-type, and it was the high concentration of these unintentional donor defects that prevented AlGa_xN from being used to manufacture practical devices for many years. Recent advances in growth techniques of AlGa_xN films have dramatically reduced the concentration of the unintentional donors [3]. Yet, residual defects remain very much an issue, and their origin is unclear. They have often been attributed to nitrogen vacancies [4]. So far, few investigations of localized centers in AlGa_xN have been reported. A comprehensive study using optical measurements of electrically and optically active defects in AlGa_xN layers in a wide range of compositions was reported in Ref. [5]. However, much work must still be

done in order to understand the influence of point defects on the electrical properties of AlGa_xN.

In this work, we report results from electrical measurements on metalorganic chemical vapor deposition (MOCVD)-grown Al_xGa_{1-x}N samples with Al content $x = 0.1$ and 0.3 . We observe a dominant donor level and show that its activation energy depends on the Al mole fraction. In samples with $x = 0.3$, we argue that the surface is rough due to the rather high Al mole fraction and therefore, they behave as interfacial layers with defects which induce a long-time relaxation in the samples.

2. Experimental

Epitaxial layers of Al_xGa_{1-x}N were grown on GaN substrates by the EMCORE Corporation using MOCVD. The thickness of the layers was about 1.6 μm. Two samples labeled sample 1 and sample 2 with Al molar fraction $x = 0.1$ and 0.3 , respectively, were investigated. The free electron concentrations obtained by Hall measurements were 2.4×10^{17} and

E-mail address: seghier@hi.is (D. Seghier).

$5.2 \times 10^{17} \text{ cm}^{-3}$ in the two samples, respectively. The samples were cleaned with organic solvents before evaporating the metal contacts in a vacuum chamber. For Ohmic contacts, Al was evaporated on the AlGaN layer, which was subsequently annealed at 750°C for 1 min. Au was evaporated on the AlGaN layer as a Schottky contact. Conventional current–voltage ($I-V$) and capacitance–voltage ($C-V$) measurements were used to investigate the Schottky diodes and a standard deep-level transient spectroscopy (DLTS) setup, to characterize deep defects. The capacitance of the diodes was also measured as a function of the temperature at various frequencies.

3. Results and discussion

We measured the capacitance variation as a function of temperature at different AC frequencies in the samples. Fig. 1 shows the capacitance vs. temperature spectra measured at 100 kHz with a bias of 0 V for samples 1 and 2. After a smooth decrease between room temperature and approximately 160 K, the capacitance drops abruptly to a level at which it remains at lower temperatures. A corresponding drop of capacitance occurs at a lower temperature in sample 2. The $C-V$ measurements indicate that the samples are not completely depleted at 80 K since the capacitance still changes with reverse bias. Hence, we deduce that the abrupt decrease in capacitance is not due to a complete freeze-out of free carriers. From conductance vs. temperature measurements (not shown), we observe a peak at low temperature in both the samples. The

position of this peak is shifted to a lower temperature in sample 2. The temperature at which the conductance peak is observed corresponds to the inflection point in the capacitance vs. temperature spectra. The activation energies deduced from the plots of $\log(\omega/T^2)$ vs. $1/T$, where ω is the angular frequency of the AC signal and T the temperature, are 90 and 110 meV for the two samples, respectively.

From the $I-V$ measurements, we calculated the Schottky barrier height $\Phi_b = 0.9$ for sample 1 and 1.5 eV for sample 2, respectively, as described in Ref. [6]. For sample 1, the value of the barrier height agrees with Schottky's rule: $\Phi_b = \Phi_m - \chi$, while for sample 2, the value is lower than that predicted by this rule.

In Fig. 2, we show a $C-V$ plot for sample 2. The reverse voltage was scanned from 0 to 4.5 V (curve a) and after waiting for 30 min, the voltage was scanned back from 4.5 to 0 V (curve b). The capacitance decreases with increasing reverse bias as expected for a Schottky diode. However, it is important to notice that there is a hysteresis between the two curves. If one keeps the reverse bias applied to the diode constant, then the capacitance increases slowly until it reaches a saturation value. The relaxation time is longer at lower temperatures. The $C-V$ curves measured in sample 1 did not exhibit a significant hysteresis.

Fig. 3 shows the DLTS spectra measured from samples 1 and 2. For these measurements, a reverse bias of 2 V and a filling pulse of 1 V were used. Under these conditions, the investigated area is far from the interface which, however, may slightly contribute to the signal. It is clear that the DLTS signal is larger in sample 2 than in sample 1. In addition, the signal is broad and does not shift in temperature when the rate window is

Fig. 1. Capacitance vs. temperature measured at 100 kHz (a) from sample 1 and (b) from sample 2. The capacitance has been normalized to its value at room temperature.

Fig. 2. $C-V$ plots from sample 2: (a) from 0 to 4.5 V; (b) from 4.5 to 0 V. The dotted arrow corresponds to a waiting time of 30 min.

Fig. 3. DLTS spectra for (a) sample 1 and (b) sample 2. Reverse bias was 2 V and filling pulse 1 V.

Fig. 4. DLTS spectra from (a) sample 1 and (b) sample 2. Reverse bias was 2 V and filling pulse 2 V.

changed as a signal related to a single energy level should do. Rather, it behaves as a signal arising from a continuum of energy levels in the band gap, for instance, interface states. In Figs. 4 (a) and (b) we show the DLTS spectra from samples 1 and 2, respectively, measured using a reverse bias of 2 V and a filling pulse of 2 V. The larger filling pulse ensures that the investigated area includes the interface between the metal and the semiconductor. While the amplitude of the DLTS signal of sample 1 is similar to the case of Fig. 3, it increases significantly for sample 2. Since the interface is included in the investigated area, we deduce that the defects responsible for the observed signal have a higher density at the interface for sample 2. Therefore, we assign the observed signal to a continuum of interface defects.

The admittance spectroscopy measurements clearly show the presence of a dominant donor level. The magnitude of the decrease in capacitance suggests that this is a dominating donor level. According to the $C - V$ measurements performed at low temperature, the samples are still conductive after this donor level becomes neutral. Hence, we deduce that this is not the shallowest donor in the samples. Alternatively, it might be the shallowest donor level in which case, there must be hopping conductivity at low temperatures in the samples. From the present data, it is difficult to conclude about the origin of the electrical conductivity of AlGaIn at low temperatures. The activation energy of the dominating donor level is lower in the sample with higher Al content (sample 2). This may explain why the electron concentration is higher in this sample at room temperature.

The DLTS measurements strongly suggest the presence of a continuum of energy levels at the interface with higher density in sample 2. We believe that the high

Al content results in a perturbed and rough surface causing these states. The potential fluctuation model proposed by Werner and Guttler [7] in a study of PtSi/Si diodes predicts that a deformation of spatial barrier distribution on inhomogeneous Schottky contacts may cause the difference in the values of Φ_b determined by $I - V$ measurements. Their model seems to be appropriate for the interpretation of the difference of the Φ_b values of AlGaIn in our study. The surface, thus, acts as an interfacial layer, which lowers the barrier, as pointed out in the model of Bardeen [8]. This would explain why we measure a lower value of Φ_b than that predicted by Schottky's rule in sample 2. The situation is different for sample 1 since it has a lower Al content. The continuum of energy levels in the band gap within this interfacial layer, which to some extent is similar to a MIS structure, is also responsible for the long-time relaxation observed in the $C - V$ plots. We do not believe that the reason for a low value of Φ_b in our samples with high Al content is a usual interfacial layer, that is an oxide layer or a damaged surface. If this were the case, samples with low x should also exhibit the same behavior.

4. Conclusion

Au/AlGaIn Schottky diodes were characterized using electrical methods for $x = 0.1$ and 0.3 . We observed a dominating donor level with activation energy dependent on the Al mole fraction. It is deeper in the sample with less Al content, which may explain the lower free electron concentration at low temperature in this sample. A barrier height lower than that predicted by Schottky's rule was measured in the sample with $x = 0.3$, and the $C - V$ characteristics exhibit a hysteresis

due to a long time relaxation process. The DLTS measurements reveal the presence of a continuum of energy levels in the band gap at the interface. The density of these states is higher in the sample with higher Al content. We attribute the lowering of the barrier in the sample with higher Al content to spatial fluctuations of Φ_b at the surface caused by the high Al content. The surface is, therefore, rough and behaves as an interfacial layer, which pins the Fermi level. Charging of this layer has a long time constant and, therefore, it is responsible for the hysteresis observed in the $C - V$ characteristics.

Electronic levels of isolated and oxygen-perturbed hydrogen in silicon and migration of hydrogen

Abstract

The migration of monatomic hydrogen in crystalline silicon is governed by three potential energy surfaces corresponding to the three possible charge states of hydrogen. The H^0 and H^+ surfaces have minima at the bond-centre site (BC) and give rise to a donor state, whereas the H^- surface has minimum at the interstitial tetrahedral site (T) giving rise to an acceptor state. We review the current experimental status regarding these surfaces. The BC-donor and the T-site acceptor are found to exist in two closely related forms, which we explain by a distortion of the energy surfaces when hydrogen is trapped in the silicon lattice at the nearby interstitial oxygen. We show how this oxygen distortion acts as a catalyst for the conversion from H^- at T sites to H^+ at BC sites and retards the migration of H^+ through BC sites. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Deep levels; Silicon; Hydrogen; Oxygen

1. Introduction

The structure of isolated monatomic hydrogen embedded in crystalline silicon has been examined theoretically by several groups [1]. The consensus has emerged that the embedded hydrogen may exist in three charge states: H^- , H^0 , and H^+ . The total energy surface of the negative charge state has minima at tetrahedral interstitial sites (T) of the silicon crystal, whereas the neutral and positive charge states have minima at bond-centre sites (BC). The migration of hydrogen is governed by these surfaces. Experimentally, we may visualise this in terms of potential energy curves connecting the neighbouring BC and T sites in configuration space. In the present contribution, we collect the available experimental data regarding the monatomic hydrogen structures in silicon. We show that the configuration potentials of all three charge states become distorted in the vicinity of an interstitial oxygen impurity in the silicon crystal and discuss the consequences of this for hydrogen migration at low temperature.

2. The configuration potentials

The Fermi-level position determines the energetically most favourable charge state of monatomic hydrogen in silicon. According to theory [1] this implies that negatively charged hydrogen at or near the interstitial tetrahedral site is the most stable configuration in n-type material. We denote this configuration $H^-(T)$. Similarly, the configurations with neutral or ionised hydrogen at the bond-centre site are denoted by $H^0(BC)$ and $H^+(BC)$. The total energy of $H^0(BC)$ exceeds that of $H^-(T)$ in n-type silicon. However, $H^0(BC)$ may still coexist with $H^-(T)$ as a metastable configuration at low temperature. This metastable hydrogen defect gives rise to a donor level defined by the emission process $H^0(BC) \rightarrow H^+(BC) + e_c$. All the features mentioned are well established theoretically and experimentally. The donor emission signal is known from capacitance spectroscopy, and the barrier for the conversion $H^0(BC) \rightarrow H^-(T)$ has been established from the annealing of this signal. Fig. 1 depicts the complete configuration scheme of monatomic hydrogen as it emerges when all the available experimental data are used for its construction. It contains the basic features outlined

Fig. 1. Configuration diagram for the three charge states of isolated and oxygen-perturbed monatomic hydrogen in the silicon lattice. The zero of the energy scale has been chosen to be equal to the total energy of neutral hydrogen at the bond-centre position.

above and includes a set of potential curves indicating how these curves may be affected for hydrogen in the strain field of interstitial oxygen. A configuration scheme similar to that of Fig. 1 has been introduced earlier [2]. In this scheme, the H^- curves were tentative. With new data available regarding the acceptor states we review the main points in the construction of the configuration potentials and quantify the scheme further. We shall anticipate the conclusions and denote the oxygen perturbed minimum-energy configurations $H^-(T)-O_i$, $H^0(BC)-O_i$, and $H^+(BC)-O_i$.

In the previous work [2] the dynamic properties of the $H(BC)$ and $H(BC)-O_i$ donor centres were examined by the application of deep level transient spectroscopy (DLTS). The characteristics related to the formation of $H(BC)$ and $H(BC)-O_i$ are particularly relevant and may be summarised as follows. Both centres are abundant after low-temperature proton implantation giving rise to two signals, denoted by $E3'$ and $E3''$, observed when DLTS is applied in situ to as-implanted samples. The $H(BC)$ and $H(BC)-O_i$ centres are always present after implantation into the depletion layer of a reverse-biased diode. However, they are almost indistinguishable as far as their electronic properties (i.e. their DLTS signals) are concerned but can be discerned on the basis of characteristic differences in their formation and annealing properties. A key point for the assignment of oxygen to the perturbed centre is that $H^+(BC)-O_i$ converts to $H^+(BC)$ in oxygen-poor material, whereas in oxygen-rich material the reverse process occurs. A quantitative analysis of these thermal processes fixes the barrier for jumps between adjacent $H^+(BC)$ configurations to about 0.44 eV and shows that $H^+(BC)-O_i$ is stabilised by an additional energy of about 0.29 eV relative to the $H^+(BC)$ as indicated in the diagram. As a consequence of the perturbation the $H(BC)-O_i$ centre should have a lower symmetry than the $H(BC)$ centre. We have confirmed this by the application of

Fig. 2. Laplace DLTS spectra revealing the trigonal symmetry of the centre associated with the $E3'$ signal, and lower symmetry of the centre associated with the $E3''$ signal (inset).

uniaxial-stress DLTS. Fig. 2 depicts the preliminary stress data. The split pattern of the $E3'$ emission signal reveals the expected trigonal symmetry of $H(BC)$, whereas the splitting under $\langle 100 \rangle$ stress of the $E3''$ signal into two components indicates a lower (monoclinic-I) symmetry as expected for $H(BC)-O_i$. In the diagram (Fig. 1) the $H^+ + e_c$ total energy curves are fixed relative to the $H^0(BC)$ point. The almost equal activation energies of $E3'$ and $E3''$ (0.175 eV) are reflected by an equal separation at BC and BC(O) of the H^0 and H^+ curves.

To place the H^- curves, we note [2] that when the bias is removed at low temperature (< 70 K) the $E3''$ signal disappears instantaneously while the $E3'$ is unaffected. If the temperature is raised to 120 K then also $E3'$ disappears swiftly. However, the total strength of the original $E3' + E3''$ signal can be recovered. The tracking of charge accumulated in the depletion layer shows that both centres prior to the recovery have been converted temporarily into negative singly charged centres which anneals at ~ 250 K. If we assume that these hidden centres can be identified with the occupied acceptor states of near T-site hydrogen, $H^-(T)$ and $H^-(T)-O_i$, we may expect the annealing to be triggered by thermal electron emission from these states. The emission may then be observed as a capacitance transient at temperatures slightly below 250 K. Since $E3' + E3''$ completely dominates the DLTS spectra and can be recovered fully from the hidden centres, we may expect a substantial signal, large enough to be detected as a single-shot capacitance transient. As depicted in Fig. 3, such capacitance-transient measurement allowing for long decay times does indeed reveal the emission. The transient shown has been recorded with an oxygen-rich hydrogen-implanted diode with about 55% of the implants initially present as $H(BC)$ and the rest as

Fig. 3. Single-shot capacitance transient at 242 K revealing two components AT' and AT''. As inset, the Arrhenius analysis of AT''(▽) and AT'(Δ). The data (●) of Refs. [3,4] have been included.

H(BC)–O_i. Both centres were first converted into the negative hidden centres by bias-removal at 110 K. The capacitance transient was then recorded after reapplication of the bias at 242 K. As can be seen the transient consists of two exponential components of about 55% and 45% intensity. We ascribe the fast decay (55%) to electron emission from H[–](T) and label it AT'. The slow decay (45%) is analogously ascribed to emission from H[–](T)–O_i and labelled AT''. These assignments are based on the following observations: (1) The negative centres can be (partially) recovered after the application of a filling pulse and a second-shot transient recorded. This second-shot transient is still composed of AT' and AT''. However, now AT'' dominates. (2) For samples prepared so that essentially only H[–](BC)–O_i is present initially, the fast component AT' is absent in the first-shot transient.

From the transients AT' and AT'' measured at different temperatures we derive the Arrhenius plots depicted as an inset in Fig. 2. We note the agreement over many decades between our AT'' data and those obtained by Johnson et al. [3,4]. The linear-regression analysis yields the activation $\Delta H'' = 0.79 \pm 0.03$ eV for the emission from H[–](T)–O_i, and $\Delta H' = 0.65 \pm 0.10$ eV for the emission from H[–](T). The electron emission enthalpies found for H[–](T)–O_i and H[–](T) exceed those of the corresponding BC donor states in accordance with the expected negative-U property.

The negative-U property implies that H⁰(BC)–O_i and subsequently H[–](BC)–O_i, are swiftly formed after thermal electron emission from H[–](T)–O_i. In accordance with this the AT'' transient should have twice the amplitude of the E3'' transient. We find that the AT'' amplitude is larger than that of E3'' but only by a factor of about 1.5. We note that the barrier (0.79 eV) for the

emission from H[–](T)–O_i is larger than the barrier (0.73 eV) for release of hydrogen from H[–](BC)–O_i, as indicated by the H⁺ potential shown in Fig. 1 and discussed above. As a result the two-step emission H[–] → H⁰ + e[–] → H⁺ + 2e[–] from the T(O) site is followed by leakage of hydrogen away from the BC(O) site which accounts at least partly for the amplitude loss.

According to the diagram the energy of H⁰(BC)–O_i is lowered to about 0.3 eV with respect to the regular sites. This supports our anticipation that the emission from H(T)–O_i is followed by a swift transformation to H⁰(BC)–O_i so the first emission step may define an acceptor level as the energy difference between H⁰(BC)–O_i + e_c and H[–](T)–O_i in the usual sense. For this, we obtained the barrier for capture into H[–](T)–O_i from H⁰(BC)–O_i + e_c. This barrier (about 0.11 eV) is included in the H⁰ potential (Fig. 1) and subtracted from the AT'' activation energy to fix the H[–](T)–O_i point in the diagram corresponding to an acceptor level at 0.68 ± 0.08 eV below the conduction band.

For the solution-site H[–](T) the situation is more complicated. We obtained an activation enthalpy ΔH of about 0.65 eV but must use indirect arguments to estimate the level position. As mentioned earlier, we found that repeating the transient causes the H[–](T)–O_i signal to dominate. This indicates that the solution-site activation enthalpy is actually the barrier against the release of hydrogen from H[–](T) to migrate as H⁰ through T sites. This migration may proceed swiftly as has been shown [2], and is indicated in the diagram by the small barrier between adjacent T sites. Most of the released hydrogen eventually traps at the oxygen-perturbed BC sites as H[–](BC)–O_i in the depletion layer of a reverse-biased diode at low temperature. The consequence of the analysis is that the concept of an acceptor level defined as the energy difference between H⁰(BC) + e_c and H[–](T) loses its meaning in practical terms, since it cannot be realised experimentally. Nevertheless, we may obtain an estimate for the total energy of H[–](T). The activation enthalpy for H⁰(BC) → H⁰(T) is known (0.295 eV), and the barrier has been estimated for the reverse process H⁰(T) → H⁰(BC) to be ~0.2 eV. Both are included in the H⁰ potential [2]. Furthermore, the swift diffusion observed under carrier injection [2] indicates a very small barrier of <0.1 eV for migration of H⁰ through T sites. In combination with the measured activation enthalpy these figures show that the total energy of H[–](T) is 0.40–0.60 eV lower than that of H⁰(BC) + e_c. This concludes the construction of the configuration diagram.

3. Low-temperature migration

With the configuration scheme at hand we may now quantify the properties of low-temperature hydrogen

migration. There are four essential points to make. (i) The barrier for migration of the neutral species H^0 in the open areas of the lattice through T sites is extremely low. This is confirmed theoretically by several authors [1], and, in particular, by recent molecular dynamics simulations [5,6], (ii) the barrier for jumps of H^0 from a T sites to a BC site is considerable. This point is still debated [3,4,7] and is crucial for the path of low-temperature migration, (iii) the strain field around defects (here oxygen impurities) influences the stability of hydrogen at BC and T sites, and (iv) the inversion of the donor and acceptor levels of monatomic hydrogen combined the effective negative-U behaviour of hydrogen at the perturbed site.

The characteristic migration cycle involving the trapping and mobilisation of hydrogen at low temperature is revealed clearly by the in situ DLTS data. Typically, after implantation at 60 K into the depletion layer of a reverse biased diode build on n-type silicon, the original signal $E3' + E3''$ associated with $H^+(BC)$ and $H^+(BC)-O_i$ accounts for > 80% of the implanted protons. After low-temperature zero-bias annealing of these signals total recovery can be achieved by illumination of the annealed sample while under reverse-bias. In this case, the restored signal is practically all $E3''$ which accounts for all of the original signal or even more. Also, the original $E3'$ signal can be recovered. This happens when the forward-bias injection of holes is applied to p⁺n-samples. In this case, $E3''$ is not recovered. However, the remaining strength of the original signal can be recovered as $E3''$ when subsequently the reverse-bias illumination is applied. The $E3'$ recovery is accompanied with long-range diffusion even at 65 K, whereas long-range diffusion (i) is not observed in connection with the $E3''$ recovery. With reference to the configuration scheme we explain the long-range diffusion during injection as a result of the continuous generation of $H^0(T)$ resulting in a steady-state population of swiftly moving H^0 species that eventually convert to metastable $H^0(BC)$. Also, the illumination generates highly mobile H^0 at T sites. However, because of the reverse bias these species convert to $H^+(BC)-O_i$ as soon as the oxygen strain-field is encountered. Due to the barrier (ii) this happens effectively without forming $H^+(BC)$ via $H^0(BC)$. The $H^+(BC)-O_i$ is bound by 0.73 eV (iii). As a consequence, H^+ will be released to diffuse and drift via BC sites (and oxygen perturbed BC sites) at around 245 K, and will eventually be swept out by the electrical field of the junction, in accordance with previous studies of hydrogen mobility [8]. When hydrogen is kept as $H^-(T)-O_i$ the migration sets in at a slightly higher temperature. This indicates that the annealing is initiated and essentially controlled by the electron emission $H^- \rightarrow H^0 + e^-$. The negative-U property (iv) then ensures a rapid conversion to the H^+ diffusion stage.

The present studies apply to low temperature and high oxygen content. The experimental evidence presented in Fig. 3 indicates that the deeper of the two hydrogen centres found may correspond to the acceptor state observed by Johnson et al. [3,4]. The two experiments have much in common. In both cases monatomic hydrogen is released from traps by illumination under bias and converted to H^- by the application of a flooding pulse. In our case, the hydrogen source is oxygen-trapped hydrogen, whereas the source in the experiment [3,4] is the compensated shallow donor. The main differences are that the temperatures of illumination and signal recording are lower in our case. Considering this similarity, and the consistency of the combined Arrhenius analysis (Fig. 3) we suggest that the two sets of data may have the same origin and conclude that the oxygen-perturbed sites may play a significant role in the migration scenario even at room temperature. The crucial point is the height of the barrier opposing the transformation $H^0(T) \rightarrow H^0(BC)$ as compared to the barrier for jump between adjacent T sites. With $\sim 10^{18} O_i \text{ cm}^{-3}$ we find that a barrier difference as low as 0.15 eV would be sufficient to produce primarily $H^-(T)-O_i$ by the illumination-flooding cycle at room-temperature designed [3,4] to release hydrogen from the compensated donors. For this to be true also for oxygen-poor material ($10^{16} O_i \text{ cm}^{-3}$) the barrier difference must be larger (0.25–0.3 eV). Such large barrier difference would comply with the barrier for the process $\mu^0(T) \rightarrow \mu^0(BC)$ (0.38 eV) reported in a recent muonium study [9] and with the small barrier (0.5–0.15 eV) for H^0 migration obtained by molecular dynamics simulations [5,6]. The simulations also foresee the trapping near

Fig. 4. The formation of a carbon-hydrogen centre in carbon-rich Si (V). Compared to the formation the $H(BC)-O_i$ centre in oxygen-rich Si (Δ). Laplace spectra obtained after zero-bias annealing (110 K) of as-implanted samples and after subsequent illumination (75 K) are shown. The carbon centre is analogous to the oxygen centre and denoted by $H(BC)-C_s$ accordingly. See Ref. [11] for details.

interstitial oxygen at strained BC sites forming weakly bound hydrogen–oxygen structures. The existence of such weakly bound structures has been revealed by the identification of local vibration modes [10].

Finally, we mention that the presence of substitutional carbon in the samples may overrule the effect of oxygen. Fig. 4 depicts recent data obtained by *in situ* Laplace DLTS for float-zone samples with $1 \times 10^{17} \text{ C}_s \text{ cm}^{-3}$ after implantation of hydrogen at low temperature. The data show that the $\text{H}(\text{BC})-\text{O}_i$ donor is heavily suppressed in favour of a dominating analogous carbon-perturbed hydrogen donor. This donor transforms during zero-bias annealing to a carbon–hydrogen acceptor [11], which is stable at room temperature. The $\text{H}(\text{T})-\text{O}_i$ acceptor is suppressed correspondingly and the migration properties of hydrogen may be affected.

4. Concluding remarks

We have shown that T sites in the proximity of interstitial oxygen act as trapping centres for H^- in the same way as the BC sites with oxygen nearby act as trapping centres for H^0 and H^+ . We concluded that the thermal electron emission initiates the escape of hydrogen from the T-site traps. We obtained the acceptor level of oxygen-perturbed monatomic hydrogen and demonstrated its negative-U property. We concluded that the presence of oxygen-perturbed centres plays a crucial role for migration of hydrogen at or below room temperature. The interstitial oxygen retards the migration of H^+ and acts as a catalyst for the conversion of hydrogen from T sites to BC sites.

Abstract

We have observed the donor ($E_c - 0.22$ eV) and acceptor ($E_c - 0.16$ eV) levels related to hydrogen–carbon complexes in silicon. The donor level is only detected at low temperatures after proton implantation. This hydrogen–carbon complex irreversibly reconfigures at temperatures above 225 K to a configuration characterized by the acceptor level, which is stable up to room temperature. The same acceptor level is also observed after atomic hydrogen diffusion. We have used Laplace transform deep level transient spectroscopy (DLTS) to show the influence of uniaxial stress on the electron emission process and the effect of the stress-induced alignment for the acceptor state. The pattern of the Laplace DLTS peak splittings indicate a trigonal symmetry of the defect. First principles calculations were carried out on the hydrogen–carbon defects with a view of determining their electrical levels and stress response for comparison with the experimental results. © 2001 Elsevier Science B.V. Keywords: Hydrogen–carbon pair; Silicon; Uniaxial stress; Laplace DLTS

Hydrogen and carbon atoms are two of the most common unintentional impurities in silicon. Usually, carbon is incorporated into the crystals during growth, while hydrogen is introduced during subsequent technological processes. Hydrogen atoms form complexes with structural defects and impurities, which for shallow donors and acceptors can result in their passivation, i.e., a disabling of their electrical activity in the crystal. In the case of the initial electrically inactive iso-valent substitutional carbon impurity, the hydrogen–carbon pair formation results in the appearance of electronic energy levels in the silicon band gap [1].

There is some controversy about the donor/acceptor properties of the energy levels related to hydrogen bound to substitutional carbon in silicon [2]. In deep level transient spectroscopic (DLTS) measurements, the charge state of the defect is not determined directly. However, in most cases, the value of the directly measured carrier capture cross-section can indicate the charge of the defect. Henry and Lang [3] showed that for Coulombically attractive centres the carrier capture cross-section is expected to be $\geq 10^{-14}$ cm², while one can expect this value to be between 10^{-16} and 10^{-15} cm² for a neutral defect and $< 10^{-17}$ cm² for a repulsive centre. Alternatively, the observation of the Poole–Frenkel effect (barrier lowering in the depletion field and consequent enhancement of the emission rate) is indicative of a charged defect. However, an

enhancement of the emission rate as a function of field must be interpreted with care as other mechanisms (tunnelling and impact ionization) can produce qualitatively similar effects from neutral as well as charged centres [4,5]. In this study, two different energy levels related to hydrogen–carbon pairs in n-type silicon are reported and according to the above criteria they have been assigned to the donor and acceptor levels. For the acceptor level, a complete piezospectroscopic analysis has been performed and the results compared with theoretical modelling.

The samples used for this study were prepared from 20 Ω -cm float zone n-type silicon doped with $\sim 10^{17}$ carbon atoms cm^{-3} . All the samples were cut from the same wafer with a (110) surface orientation in the shape of $1 \times 2 \times 7$ mm blocks with the longest sample edge along one of the major crystallographic directions ($\langle 100 \rangle$, $\langle 110 \rangle$ and $\langle 111 \rangle$). Hydrogen–carbon complexes were produced by either proton implantation at 70 K under a reverse bias with the energy of ~ 525 keV and a dose of $\sim 5 \times 10^{19} \text{ cm}^{-2}$ or by wet chemical etching at room temperature (HNO_3 and HF in the ratio 10:1). Czochralski grown 20 Ω -cm n-type silicon samples were implanted with protons under the same conditions as the carbon-rich samples for direct comparison. Gold Schottky diodes were formed for DLTS measurements.

We have applied the technique of high resolution Laplace DLTS [6] in combination with uniaxial stress to carry out a piezospectroscopic analysis of the observed hydrogen–carbon complexes. The stress partially lifts the spatial degeneracy of the defect which results in a splitting of the defect energy level. Assuming a random distribution of defects in non-equivalent orientations, the number of split lines and their intensity ratios reflect the symmetry class of the initial charge state of the given defect. The relative shifts of the total energies of the non-equivalent orientations with respect to the applied stress have been determined by applying the stress at sufficiently high temperature to reach thermodynamic equilibrium, and then quickly cooling the sample to the measured temperature. Subsequently, the occupancies of the non-equivalent orientations have been evaluated, and the relative energy shifts have been obtained from Boltzmann statistics. The charge state of the complex during the alignment process is controlled by the bias applied to the sample.

Zero stress Laplace DLTS spectra obtained below 103 K after proton implantation reveal two peaks of comparable concentration in the carbon-rich samples. One of these peaks is also seen in the oxygen-rich samples and can be assigned to overlapping donor levels of isolated bond centred hydrogen ($\text{E3}'$) and bond centred hydrogen perturbed by interstitial oxygen ($\text{E3}''$) as previously discussed [7]. The other peak only appears in the carbon-rich samples. We label it CH_I . Fig. 1

Fig. 1. Arrhenius plots for the electron emission from CH_I (circles) and CH_II (squares) measured by Laplace DLTS. Activation enthalpies ΔH and pre-exponential factors R_0 are given.

shows the Arrhenius plot for the electron emission from CH_I yielding the activation enthalpy $\Delta H \approx 0.22$ eV and the apparent (intercept) electron capture cross-section $\sigma_{n,a} \approx 2 \times 10^{-14} \text{ cm}^2$ obtained from the pre-exponential factor. The pre-exponential factor is similar to the values obtained for the well-established donor levels $\text{E3}'$ and $\text{E3}''$. The ionization process for CH_I is influenced by the electric field in the space charge region, and the observed field dependence complies with the three-dimensional Poole–Frenkel effect expected for an electron trapped by a positively charged centre [4]. We conclude that CH_I is a singly charged donor.

Several properties concerning the microscopic structure of CH_I have been established. A direct comparison with the oxygen-rich samples shows that CH_I behaves dynamically like $\text{E3}''$, i.e., bond centred hydrogen perturbed by interstitial oxygen [7]. Uniaxial stress measurements did not allow us to establish the exact symmetry class of CH_I , but we can conclude that the centre has lower than trigonal symmetry. Finally, the CH_I complex irreversibly converts to another hydrogen–carbon complex after zero bias annealing at 225 K (see below). These observations are all consistent with an atomic configuration $\text{SiH}_\text{BC}\text{-SiC}_\text{s}$ in which hydrogen is bond centred between two silicon atoms located as the first and second nearest neighbour to the substitutional carbon atom.

The disappearance of CH_I in the Laplace spectrum after zero bias annealing at 225 K is accompanied by the appearance of another hydrogen–carbon related peak labelled CH_II . The conversion ratio between CH_I and CH_II is practically 1:1, indicating that CH_I reconfigures to CH_II by local, thermally activated jumps of hydrogen around carbon. CH_II is stable at room temperature and is also observed in the etched samples. The Arrhenius

plots for the electron emission from CH_{II} (Fig. 1) confirm that the levels observed after implantation followed by annealing and after atomic diffusion of hydrogen are identical. In both cases the activation enthalpy is $\Delta H \approx 0.16 \text{ eV}$. The electric field dependence of the emission process for CH_{II} was studied under exactly the same experimental conditions as for CH_{I} . No field dependence was observed. Direct capture measurements using the filling-pulse method yielded an electron capture cross-section for CH_{II} of $\sigma_n \approx 2 \times 10^{-16} \text{ cm}^2$ with no measurable energy barrier for the capture process. From the lack of field dependence and the value of the electron capture cross-section, we conclude that CH_{II} is a deep acceptor. This is supported by the pre-exponential factor of the Arrhenius plots for the emission process (Fig. 1), which is almost two orders of magnitude smaller for CH_{II} than for CH_{I} .

We have carried out a detailed piezospectroscopic analysis of the CH_{II} complex. Fig. 2 shows Laplace DLTS spectra of CH_{II} measured at 85 K under uniaxial stress along the $\langle 111 \rangle$ direction. The spectra have been obtained with stress increments of 0.025 GPa from zero stress up to 0.5 GPa. It can be seen that CH_{II} splits into two components, which move linearly with the applied stress. The amplitude ratio for the split lines is approximately 3:1, and their amplitudes sum up to the value for the unstressed sample. In a similar way, the Laplace DLTS peak splits into two components with amplitude ratio 1:1 for stress along the $\langle 110 \rangle$ direction, while no line splitting is observed for the $\langle 100 \rangle$ stress direction. This splitting pattern establishes the trigonal symmetry of the CH_{II} complex in agreement with the results reported by Kamiura et al. [8,9].

Fig. 2. Laplace DLTS spectra of the electron emission at 85 K from the CH_{II} complex under uniaxial stress along the $\langle 111 \rangle$ direction. The spectra have been obtained from zero stress (nearest to the front) up to 0.5 GPa with stress increments of 0.025 GPa. The two peaks originating from non-equivalent orientations of the CH_{II} complex are reliably resolved for stresses above 0.3 GPa.

The effect of stress on the defect total energy for a given charge state can be found from the relation $\Delta E = \sum B_{ij} \epsilon_{ij}$, where ϵ_{ij} are the components of the strain tensor and B_{ij} are the components of the corresponding piezospectroscopic tensor. For a trigonal defect stressed along the $\langle 111 \rangle$ direction, the difference in the total energy between the two non-equivalent orientations of degeneracy 1 and 3 is given by $\Delta E(1) - \Delta E(3) = 4B_{22}S_{44}P/3$, where S_{44} is a component for the silicon elastic compliance tensor ($S_{44} = 12.56 \times 10^{-3} \text{ GPa}^{-1}$), P is the stress ($P < 0$ for compressive stress), and B_{22} is the trigonal component of the piezospectroscopic tensor. The trigonal component B_{22} describes how the total energy of the defect changes when the defect is subjected to a stress along the trigonal axis, i.e., the $\langle 111 \rangle$ direction. The value of $\Delta E(1) - \Delta E(3)$ for the two charge states of the CH_{II} complex has been obtained by evaluating the relative occupancies of the two non-equivalent orientations after applying stress at $\sim 330 \text{ K}$ for sufficient time to reach the steady-state condition. From this analysis, we obtain $B_{22} = -5.3 \text{ eV}$ for the negatively charged centre (no bias applied during the alignment) and $B_{22} = -1.9 \text{ eV}$ for the neutral centre (reverse bias applied during the alignment). The negative value of B_{22} shows that the total energy of the CH_{II} complex is increased by compressive stress applied along the trigonal axis of the defect. We conclude that the relaxation of the CH_{II} complex along the trigonal axis is outward.

Theoretical modelling has been performed to investigate our hypothesis that the $E_c - 0.22 \text{ eV}$ donor level (CH_{I}) relates to the $\text{SiH}_{\text{BC}}\text{SiC}_s$ configuration of the hydrogen-carbon pair. Local density functional theory using both cluster and supercell geometries with a Gaussian basis set [10,11] has been applied. It has been found that the calculated donor level of $\text{SiH}_{\text{BC}}\text{SiC}_s$ lies at $E_c - 0.21 \text{ eV}$, i.e. very close to the observed value for the CH_{I} level. Further indirect evidence also exists for the assignment of CH_{I} with $\text{SiH}_{\text{BC}}\text{SiC}_s$, as this structure has previously been observed in proton-implanted material by Hoffmann et al. [12] by infrared absorption. As in the present work, it was observed by Hoffmann et al. that the $\text{SiH}_{\text{BC}}\text{SiC}_s$ configuration (responsible in our case for the donor level CH_{I}) disappears after annealing at $\sim 225 \text{ K}$.

The microscopic picture of the configuration responsible for the acceptor state CH_{II} is somewhat ambiguous. Both $\text{SiH}_{\text{BC}}\text{C}_s$ (bond centred hydrogen adjacent to the carbon) and $\text{SiC}_s\text{H}_{\text{AB}}$ (hydrogen anti-bonded to the carbon) have a trigonal symmetry and are predicted by our calculations to possess acceptor levels close to that observed for CH_{II} as shown in Table 1. However, the calculated piezospectroscopic parameters of $\text{SiC}_s\text{H}_{\text{AB}}$ in the neutral and negative charge states are in closer agreement with those observed by defect alignment (Table 1). The calculated formation energies for the

Table 1

Theoretical values of the acceptor levels and the piezospectroscopic parameters related to two different trigonal configurations of the hydrogen-carbon pair compared to the experimental values. The electrical levels are calculated with an error of ± 0.2 eV, while the theoretical stress behaviour is accurate to $\sim 20\%$

	Theory (eV)		Experiment (eV)
	SiH _{BC} C _s	SiC _s H _{AB}	CH _{II}
(- / 0) Level	0.15	0.33	0.16 ± 0.01
B_{22} (negative)	-6.0	-4.8	-5.3 ± 0.2
B_{22} (neutral)	-4.5	-2.8	-1.9 ± 0.2

SiH_{BC}C_s and SiC_sH_{AB} configurations in the negative charge state were found to be similar (within the calculation error). As a result, despite the fact that the measured piezospectroscopic parameters, when compared to the theoretical values for both configurations, might favour the SiC_sH_{AB} assignment this is far from conclusive. However, the convergence of the experimental and theoretical results strongly support the assignment of the acceptor level to either SiH_{BC}C_s or SiC_sH_{AB} and due to the similarities of the formation energies it seems likely that the trigonal centre observed by us is a mixture of both configurations.

In summary, two hydrogen-carbon related electrical levels have been observed in proton implanted n-type silicon. The first of these, the low symmetry donor CH_I, we assign to hydrogen trapped between two silicon atoms perturbed by a nearby substitutional carbon atom. The second centre, the trigonal acceptor CH_{II}, we

assign to hydrogen bonded directly to substitutional carbon.

Formation mechanism of hydrogen-induced (1 1 1) platelets in silicon

Taejeon 305-701, South Korea

Abstract

We suggest a structural model for the formation of hydrogen-induced (1 1 1) platelets in Si. We calculate the formation energies of various platelet structures using the first-principles pseudopotential method within the local-density-functional approximation. The formation mechanism involves a structural transformation from a double-layer- H_2^* structure into an H-saturated Si(1 1 1) internal surface structure with H_2 molecules generated in the platelet void. We also examine the energetics of the H-saturated Si(1 1 1) internal surface structures with various densities of H_2 molecules, and find an abrupt increase of the internal pressure built up in the void. © 2001 Elsevier Science B.V. Keywords: Silicon; Hydrogen; Platelets

Hydrogen-induced platelets of a few tens of nanometers have been observed in heavily hydrogenated silicon crystals [1]. These platelets are basically extended planar defects with orientations along the crystalline planes of (1 0 0) and (1 1 1) [1–3]. Experiments have confirmed that the platelets consist of Si–H bonds, but their atomic structure is still a subject of interest.

To explain the structure and formation mechanism of the (1 1 1) platelets, several experimental and theoretical studies have been done. Recent theoretical calculations suggested that in the (1 1 1) platelets, an (1 1 1) monolayer of Si vacancies is decorated by H atoms, forming the so-called V platelets [4]. High-resolution transmission electron microscopy (HRTEM) images showed that H atoms saturate the broken bonds between adjacent (1 1 1) planes, suggesting an H-saturated internal (1 1 1)-surface structure $([2Si-H]_n)$ [5]. Based on H_2^* aggregates, Zhang and Jackson examined various structural models

such as single-layer- H_2^* ($[H_2]_n^S$), staggered- $[H_2]_n^S$, and double-layer- H_2^* ($[H_2]_n^D$) structures, and suggested that the $[H_2]_n^D$ structure is favorable for the (1 1 1) platelets [6].

In this work, we study various (1 1 1) platelet structures in Si, and propose a structural model for the formation of the (1 1 1) platelets, where the $[H_2]_n^D$ structure [see Fig. 1(a)] is initially formed and eventually transformed into the $[2Si-H]_n$ structure, with H_2 molecules accumulated in the interstitial region of the platelet [see Figs. 1(b)–(d)]. We also investigate the dependence of lattice dilation along the [111] direction on the density of H_2 molecules in the platelet void.

The total energies are calculated using the first-principles pseudopotential method within the local-density-functional approximation (LDA) [7]. The wave functions are expanded in a plane-wave basis set with a kinetic energy cutoff of 25 Ry. Details of the method have been given elsewhere [8].

We calculate the formation energies for various (1 1 1) platelet structures as a function of lattice dilation along the [111] direction (see Fig. 2). Among the three H_2^*

Fig. 2. The formation energies of various platelet structures plotted as a function of dilation length.

aggregates, the $[H_2]_n^D$ structure is lowest in energy. With zero dilation, vacancy-related $[VH_4]_n$ and $[V_2H_2]_n$ structures [4], where vacancy layers are decorated by H atoms, are found to be more stable than the $[H_2]_n^S$, staggered- $[H_2]_n^S$, $[H_2]_n^D$, and $[2Si-H]_n$ structures. The energy of the $[V_2H_2]_n$ structure is lower by about 0.4 eV than for the $[H_2]_n^D$ structure, and this energy is nearly independent of dilation length. However, as the dilation length increases, the vacancy-related structures become less stable, because the energies of the $[H_2]_n^D$

and $[2Si-H]_n$ structures decrease very rapidly. In addition, since it requires very high activation energies of 2.5–5 eV [4], the $[H_2]_n^D$ structure is considered to be energetically more favorable than the $[V_2H_2]_n$ structure for small dilation lengths. In fact, the (111) platelets have been observed predominantly in H-plasma treated samples, where the concentrations of vacancies and interstitials are extremely low [1]. At a dilation length of 2.2 Å, the $[2Si-H]_n$ structure is stabilized against the $[H_2]_n^D$ structure, with almost no interactions between the two facing H planes. As the lattice is expanded further above 2.7 Å, the $[2Si-H]_n$ structure becomes less stable than the $[H_2]_n^D$ structure.

The $[2Si-H]_n$ structure is extremely unstable for small lattice dilations because of the repulsive interactions between the two facing Si-H bond layers. When H_2 molecules are accumulated in the void region of the $[2Si-H]_n$ structure, the formation energy is slightly reduced. When the $[2Si-H]_n$ structure contains an H_2 molecule per two Si-H bonds, it has the same number of H atoms as the $[H_2]_n^D$ structure, with the molecule concentration of $7.83 \times 10^{14} \text{ cm}^{-2}$. This $[2Si-H]_n$ structure with H_2 molecules in the void is found to be lowest in energy for lattice dilations above 1.7 Å, as shown in Fig. 2. In this case, our LDA calculations show that the energy difference between the $[2Si-H]_n$ structure with H_2 molecules and the $[H_2]_n^D$ structure is just a few tens of meV for dilation lengths around 2 Å. With increasing the kinetic energy cutoff to 64 Ry, we find that the GGA calculations give the energy difference of about 0.1 eV at a dilation length of 2.3 Å, which is slightly increased, as compared to the LDA results. In the GGA calculations, we calculate the dilation length of 1.6 Å, where the $[2Si-H]_n$ structure with H_2 molecules becomes more stable than the $[H_2]_n^D$ structure, similar to the LDA estimate. Thus, we conclude that the LDA calculations describe correctly the energetics of various H-induced (111) platelet structures considered here.

Based on our calculations, we address that the formation of the (111) platelets is accompanied with the structural transformation from the $[H_2]_n^D$ structure into the $[2Si-H]_n$ structure with H_2 molecules, which is derived by increasing the lattice dilation. In this process, the activation energy is calculated to be about 1.8 eV [8]. The $[2Si-H]_n$ structure with H_2 molecules in the platelet void is consistent with recent HRTEM measurements, which exhibited the structure of atomic ledges on the (111) plane with broken bonds [5]. The HRTEM images also revealed a step structure in the (111) platelets [5]. When the $[H_2]_n^D$ structure is transformed into the $[2Si-H]_n$ structure with H_2 molecules, one of the two broken layers in the $[H_2]_n^D$ structure is recrystallized. If this recrystallization occurs in different broken layers in different regions, a step structure will be naturally formed.

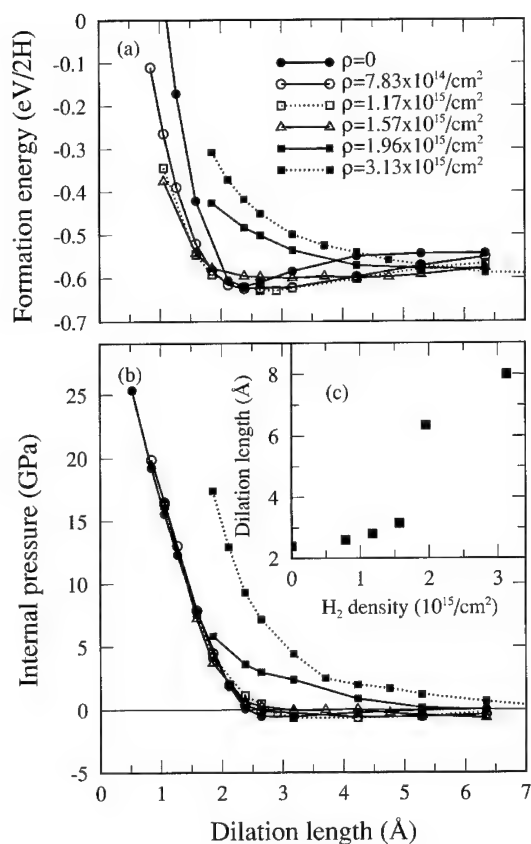

Fig. 3. The (a) formation energies and (b) internal pressures of the $[2\text{Si-H}]_n$ structures with various densities of H_2 molecules in the platelet void plotted as a function of dilation length. (c) The equilibrium dilation lengths at zero pressure drawn for various densities of H_2 molecules.

From the derivative of the total energy with respect to dilation length, we can estimate the pressure built up in platelets. At zero dilation length, the $[\text{H}_2^*]_n^D$ structure experiences an internal pressure of about 14 GPa along the $[111]$ direction. For the $[2\text{Si-H}]_n$ structure without H_2 molecules, the calculated internal pressure is zero at a dilation length of about 2.3 Å. When the $[\text{H}_2^*]_n^D$ structure has one H_2 molecule per two Si-H bonds, zero internal pressure occurs at 2.6 Å.

We also examine the energetics and pressures of the $[2\text{Si-H}]_n$ structures with various densities (ρ) of H_2 molecules in the platelet void. The calculated formation energies and internal pressures are plotted as a function of dilation length in Figs. 3(a) and (b). For molecule densities up to $\rho = 1.57 \times 10^{15} \text{ cm}^{-2}$, H_2 molecules are arranged in a single layer in the void of the $[2\text{Si-H}]_n$ structure, as shown in Figs. 1(b) and (c); each molecule is positioned near a tetrahedral site in the $[2\text{Si-H}]_n$ structure. In this case, the calculated formation energies are found to be similar, almost independent of ρ , and the

equilibrium dilation lengths, where internal pressures are zero, are close to 2.5 Å [see Fig. 3(c)]. For $\rho = 1.57 \times 10^{15} \text{ cm}^{-2}$, the $[2\text{Si-H}]_n$ structure has one H_2 molecule per Si-H bond, and H_2 molecules occupy all the tetrahedral sites in a single layer. Here, the shortest distance between two neighboring tetrahedral sites is calculated to be 2.35 Å, while the average inter-molecular distance is about 2.37 Å. This small difference between the two cases is due to the slight shift of the molecular positions from the tetrahedral sites. As H_2 molecules are further inserted in a single layer of the void, the inter-molecular distance is shortened, and the single layer configuration is no longer stable.

For $\rho = 1.96 \times 10^{15} \text{ cm}^{-2}$ with three H_2 molecules per two Si-H bonds, we find that H_2 molecules are arranged in multi-layers [see Fig. 1(d)], not in a single layer, although the molecule layers cannot be defined clearly in this configuration. The dilation length, where the formation energy has a minimum value, is increased abruptly to about 6.3 Å, as shown in Fig. 3(c). Such an abrupt increase is originated from the single-layer to multi-layer transition of the H_2 molecules in the platelet void. This result indicates that as the number of H_2 molecules increases in the void, the two facing hydrogenated layers in the $[2\text{Si-H}]_n$ structure repel each other due to the increase of internal pressure. Then, the formation energy tends to increase, as illustrated in Fig. 3(a).

Electron microscopy studies combined with continuum elasticity theory showed that applied stress is 1.05 GPa for dilation lengths of 3 ± 1 Å [5]. In our calculations, when the internal pressure is 1 GPa, the calculated dilation lengths lie in the range of 2.2–2.4 Å for the densities of H_2 molecules up to $\rho = 1.57 \times 10^{15} \text{ cm}^{-2}$. For $\rho = 1.96 \times 10^{15} \text{ cm}^{-2}$, where H_2 molecules are arranged in multi-layers, the dilation length at a pressure of 1 GPa is calculated to be 4.2 Å. Thus, we suggest that the densities of H_2 molecules lie in the range of 1.57 – $1.96 \times 10^{15} \text{ cm}^{-2}$ for experimentally measured internal pressures [5]. We point out that the $[111]$ platelets contain not only the H_2 molecules generated by the structural transformation from the $[\text{H}_2^*]_n^D$ structure into the $[2\text{Si-H}]_n$ structure but also extra molecules diffused from the Si bulk region.

In HRTEM measurements [1,5], the dilation length was shown to be smaller than 1 Å, while our calculated value is 2.4 Å at zero pressure for the $[2\text{Si-H}]_n$ structure without H_2 molecules. When samples are cut for HRTEM measurements, since H_2 molecules can be extracted from the void, the dilation length may be reduced. In this case, cutting the platelets may remove the H atoms in the $[2\text{Si-H}]_n$ structure, recovering the Si-Si bonds. Thus, HRTEM images may measure just the elongated Si-Si bonds along the $[111]$ direction. However, behind the cross-sectional surface, the $[2\text{Si-H}]_n$

structure still exists, with the elongated Si–Si bonds at the surface.

In conclusion, we find that the H-induced (111) platelets are formed by a structural transformation from the $[\text{H}_2^*]_n^{\text{D}}$ structure to the $[\text{2Si-H}]_n$ structure, accompanied with the generation of H_2 molecules in the void region. The $[\text{H}_2^*]_n^{\text{D}}$ structure, which is energetically most favorable in perfect Si, is more stabilized as the lattice is expanded, which reduces the internal pressure. Since the $[\text{2Si-H}]_n$ structure with H_2 molecules is stabilized against the $[\text{H}_2^*]_n^{\text{D}}$ structure for dilation lengths larger than 1.7 Å, the $[\text{H}_2^*]_n^{\text{D}}$ structure is eventually transformed into the $[\text{2Si-H}]_n$ structure with H_2 molecules generated in the void.

Abstract

We apply a new development of density functional perturbation theory to study the vibrational properties of hydrogen-containing complexes in silicon. A conjugate gradient algorithm within the SIESTA package is used to relax the atomic structure of the complexes. Then, the dynamical matrix of the entire supercell is computed analytically and diagonalized, leading to a complete vibrational spectrum. Results for hydrogen dimers, IH_2 , VH_n ($n = 1, 2, 3, 4$) and V_2H_6 defects are presented. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Local vibrational modes; Silicon; Hydrogen

1. Introduction

Hydrogen binds covalently in the immediate vicinity of many impurities and defects and this gives rise to a number of local vibrational modes (LVMs) well separated from the bulk phonon spectra [1]. The calculation of accurate LVMs at the ab initio level is a challenge, as it provides a critical link between theory and experiment. Typical accuracies in the calculated vibrational modes are within 3–10% of experimental data, which means in some cases a deviation of over 100 cm^{-1} .

Most authors calculate frequencies within the *frozen phonon* approximation. Conventional first-principles codes are used to compute the total energy of the system in the equilibrium configuration and for small displacements of selected atoms [2–6]. We propose here a different approach, based on the density functional perturbation theory (DFPT) [7,8]. In most cases, the comparison of the calculated and measured vibrational

frequencies is very favorable, improving on the results obtained by other techniques.

2. Methodology

We use the fully self-consistent ab initio SIESTA code [9,10]. The electronic energy is obtained from density-functional theory (DFT) [11,12] within the local density approximation. The exchange-correlation potential is that of Ceperley–Alder [13]. The electronic wave function is expressed in terms of a linear combination of pseudoatomic orbitals. In the present work, a double zeta basis is used to describe the valence electrons: two sets of *s* and *p*'s on Si, two *s*'s and one set of *p*'s on H. The host crystal is represented by a periodic supercell of 64 Si atoms with \vec{k} -point sampling reduced to Γ point.

In order to determine the equilibrium structure of the defects studied, we relax all the atomic coordinates with a conjugate gradient algorithm, reaching a tolerance in the forces of 0.01 eV/\AA . The dynamical matrix for the whole cell is computed from this ground state.

A new implementation of DFPT has been developed to compute the electronic response to infinitesimal

E-mail address: pruneda@condmat.uniovi.es (J.M. Pruneda).

atomic displacements. Thanks to the ' $2n + 1$ ' theorem in DFPT, we can obtain analytically the dynamical matrix from the gradient of the density relative to *atomic coordinates*, without physically moving any atom. Note that merely linear effects are obtained in this method. Thus, one expects to obtain high-quality frequencies for the vibrational modes that are harmonic, but the frequencies of modes involving large anharmonic terms will be less accurate.

3. Results

LVMs have been studied for the H dimers (H_2 and H_2^*), the hydrogenated self-interstitial IH_2 complex, hydrogenated vacancy (VH_n , $n = 1, 2, 3, 4$) and V_2H_6 .

We focus here only on the stretching, and some bending modes of H.

3.1. Hydrogenated vacancies

In our calculations (Table 1), VH has monoclinic symmetry, and the H oscillates almost parallel to the $\langle 111 \rangle$ direction. In the orthorhombic VH_2 , the two equivalent hydrogens have stretching modes along the $\langle 100 \rangle$ and $\langle 001 \rangle$ directions. The calculated frequencies for these modes are 2121 and 2144 cm^{-1} respectively. VH_3 has C_{3v} symmetry. The A singlet involves the movement of the three H atoms towards the vacancy, while in the twofold degenerate E mode one of the atoms moves in opposition. VH_4 has T_d symmetry. In addition to the threefold degenerate mode T_2 mode at 2205, we

obtain an infra-red (IR) inactive singlet A_1 mode at 2265 cm^{-1} . V_2H_6 behaves as two weakly coupled VH_3 complexes. The vibrational modes of V_2H_6 are almost identical to those of VH_3 . The A_2 singlet at 2176 cm^{-1} induces a dipole along the $\langle 111 \rangle$ direction. In addition to this mode, and the IR-active E doublet, we obtain two IR-inactive modes at 2186 and 2134 cm^{-1} .

3.2. H_2 , H_2^* and IH_2

The trigonal H_2^* defect [17,19] consists of one hydrogen atom close to the antibonding (AB) site, and the other near the bond-centered (BC) site, forming an $Si-H\cdots Si-H$ structure. The $Si-H_{AB}$ bond length is slightly longer than the $Si-H_{BC}$ one

(1.580 \AA vs. 1.510 \AA in our calculations). This give rise to different stretch frequencies for the two atoms: 2135 cm^{-1} for H_{BC} and 1750 cm^{-1} for H_{AB} . We also obtain two nondegenerate wagging modes, both related to H_{AB} . The calculated modes with D substitutions are given in Table 2.

IR and Raman measurements of H_2 in silicon [22,25] reveal a considerable softening of the stretching mode with respect to the frequency of H_2 in the gas phase. The electron affinity of the Si atoms surrounding H_2 results in a weakening of the H–H bond and this reduces the vibrational frequencies. Even though the H–H stretch mode is not expected to be fully harmonic, our calculated frequency is close to the experimental one (Table 2) and lower than that for free H_2 (4194 cm^{-1}).

Note that D substitutions fail to show the observed anharmonic shift [22].

Finally, IH_2 has two almost equivalent weakly coupled hydrogen atoms, with very similar stretching frequencies. Our relaxed structure has almost C_{2v} symmetry, with the A mode higher than the B mode, confirming early calculations [23]. We also reproduce the correct ordering for the bending modes at 737 and 732 cm^{-1} . Note that we predict that the two H's in this defect are slightly inequivalent. Thus, we obtain two different frequencies when one of the H's is substituted by D (IHD and IDH). Experimentally, only one IHD complex is observed. However, the spectrum obtained with an H/D mix shows three H lines at 1989 cm^{-1} (IH_2), 1988 cm^{-1} (IHD), and 1986 cm^{-1} (IH_2). If the HD line belonging to IDH were at $1988 + 1 = 1989 \text{ cm}^{-1}$, it would only affect the relative amplitudes of the two IH_2 lines. Even though our predicted frequencies for this defect are remarkably good, they are not accurate to a few cm^{-1} and the slight difference between IHD and IDH which we obtain could easily be an artifact of the calculation.

4. Conclusions

We propose a new development of DFPT, using localized atomic wavefunctions as a basis set, and apply it to the study of LVMs of H-related defects in silicon. In contrast to other methods, the dynamical matrix is computed analytically without actually displacing any atom. The calculations are based on the ground state density matrix as computed with the SIESTA package.

The defects included here involve a range of Si–H bonding configurations. In situations where larger anharmonic contributions are present, the accuracy of the method decreases somewhat ($\sim 5\%$). We note that this occurs, for example, when H is close to a BC position. However, in most cases the calculated frequencies are in remarkable agreement ($\leq 3\%$) with experimental data, implying not only that this perturbative approach is totally justified, but also that the ground state density matrix calculated with SIESTA is very reliable.

Structural properties of hydrogen-induced platelets in silicon: a Raman scattering study

E.V. Lavrov^{a,b,*}, J. Weber^a^a *University of Technology, 01062 Dresden, Germany*^b *IRE RAS, 103907 Moscow, Russia*

Abstract

Different treatments of hydrogenation induce hydrogen containing plate-like defects on {111} crystallographic planes in silicon. Several structural models of the platelets were proposed of which the most prominent are: (a) A double layer of interstitial hydrogen H_2^* pairs and (b) hydrogen saturation of the Si–Si bonds at a {111} plane with H_2 molecules trapped within the platelet. Raman scattering studies reported that local vibrational modes related to the platelets appear around 2100 cm^{-1} , whereas a local mode at 4160 cm^{-1} was associated with H_2 trapped within the platelet. From an analysis of the polarized Raman scattering spectra of the 2100- and 4160-cm^{-1} bands we identify two different types of {111}-platelets described above, which exist simultaneously with concentrations depending on plasma conditions. © 2001 Elsevier Science B.V. 1. Introduction

High concentrations of hydrogen introduced into Si by plasma treatment create extended planar defects along the {111} crystalline planes, which are called platelets [1]. Electron microscopy [2], Raman scattering [3], as well as infrared absorption results [3] have shown that the fundamental blocks comprising these defects are Si–H bonds. A number of different structural models of the platelets have been suggested [2,4,5]. The most prominent of these are: a double layer of H_2^* , $[H_2^*]_n^D$, and hydrogen-saturated {111} planes, $[2Si-H]_n$, i.e., the configuration in which each Si–Si bond on an {111} plane is replaced by two Si–H bonds.

Here we present an analysis of the polarized Raman scattering spectra measured on the {111}-hydrogen-

induced platelets in Si. A first Raman scattering study by Heyman et al. showed that Raman active modes of the {111}-platelets are observed at approximately 2100 cm^{-1} [3]. Recent results by Leitch et al. showed that H_2 in the platelet has a local vibrational mode at 4160 cm^{-1} [6]. Our analysis of the 2100- and 4160-cm^{-1} bands identifies the two different types of platelets described above, which exist simultaneously with concentrations depending on the plasma conditions.

2. Experimental

Silicon samples used in this study were n-type, phosphorus-doped, Cz (100)-wafers with resistivity of $0.75\text{ }\Omega\text{ cm}$. Hydrogen was introduced into the Si samples by means of a remote Dc-plasma system with sample temperature varied between room temperature to 300°C for a duration of 30 min–6 h.

The details of the Raman setup are described elsewhere [6]. Polarized Raman spectra were collected in a pseudobackscattering geometry. The polarization

geometry is defined with respect to the sample surface (1 0 0): the x -, y -, and z -axis are parallel to [1 0 0], [0 1 0], and [0 0 1], while y' - and z' -axis are parallel to [0 1 1], and [0 $\bar{1}$ 1]. In the notation $\{a[b, c]d\}$, $a(d)$ refers to the propagation vector of the incident (scattered) light, while $b(c)$ refers to the polarization vector of the incident (scattered) light. As usual, the depolarization ratio, Δ , is defined as the ratio of the scattered light intensity polarized perpendicular to the excitation light, E^{in} , to the intensity parallel to E^{in} . In the notation $\Delta_{[xyz]}$, the subscript implies that the excitation light is polarized along the $[xyz]$ -axis.

3. Results

Fig. 1 shows room temperature polarized-sensitive spectra of a Si sample after exposure to hydrogen plasma at 150°C for 6 h. The broad band at 2100 cm^{-1} was previously assigned to the {111}-platelets [3], whereas the band lying at 4160 cm^{-1} was associated with H_2 trapped within platelets [6]. The polarized spectra of the 2100- cm^{-1} band shown in the figure are in qualitative agreement with previous data reported by Heyman et al. [3], i.e., $\Delta_{[110]} = 0$, which suggests the fully symmetric mode of a trigonal defect [7]. In the following discussion we want to consider only the value of $\Delta_{[110]}$ because both the 2100- and 4160- cm^{-1} bands, regardless of the conditions of the samples preparation, display $\Delta_{[110]} = 0$.

Fig. 1. Room temperature polarized Raman spectra after exposure to hydrogen plasma at 150°C for 6 h. Polarization geometry is defined with respect to the sample normal [1 0 0]. Spectra are offset vertically for clarity. Note that the intensity in the spectral range 1900–4300 cm^{-1} was scaled up by factor of 10.

As follows from the figure, $\Delta_{[110]}$ of the 2100- cm^{-1} band is close to one, whereas Heyman et al. reported $\Delta_{[110]} \cong 0.3$ [3]. Another striking feature is that the polarization properties of the 4160- cm^{-1} band are precisely the same as that of the 2100- cm^{-1} one. This may lead to the conclusion that H_2 is aligned along the [1 1 1] axis and, therefore, the 4160- cm^{-1} band displays the properties of the fully symmetric mode of a trigonal defect.

However, this assignment meets serious difficulties. According to calculations, H_2 positioned at the tetrahedral site of the perfect Si lattice has extremely small barriers for rotation [8]. As compared to the T_d site, H_2 in platelets is well isolated from the surrounding lattice and thus should rotate freely. The less obvious problem with the suggestion of aligned H_2 comes from the value of $\Delta_{[110]}$. With the known Raman tensor of free H_2 [9], $\Delta_{[110]}$ should be equal to 0.021, well below the experimental value.

All these problems can be solved if we model the platelet as a flat infinitely thin dielectric layer described by an isotropic, frequency-independent, real dielectric constant ϵ . This model takes into account deviation of the local electric field within the platelet from that of the incident electric field in the bulk of the sample.

According to the formalism proposed by Reed et al. [10], the local electric field in the platelet, E^{loc} may be written as

$$E^{\text{loc}} = A(\theta_{\text{in}}, \omega_{\text{in}}) E^{\text{in}}. \quad (1)$$

Matrix A is a function of the polar angle θ_{in} , measured with respect to the platelet normal, frequency of the excitation light, ω_{in} , and ϵ . The induced polarization \mathcal{P}^i of the oscillating Raman dipole is related to the local macroscopic electric field through the Raman tensor of the scatterer α^i , $\mathcal{P}^i = \alpha^i E^{\text{loc}}$, where i is either Si-H, or H_2 . If z is the bond axis, then α^i is diagonal and $\alpha_{xx}^i = \alpha_{yy}^i = \delta^i$, $\alpha_{zz}^i = 1$, where δ^i is bond anisotropy defined as the ratio of the dynamic molecular polarizabilities perpendicular and parallel to the bond axis. Thus, the electric field in the bulk of the sample E^{out} radiated by polarization \mathcal{P}^i with frequency ω_{out} in the direction making polar angle θ_{out} with the platelet normal, is given by

$$E^{\text{out}} = \frac{\omega_{\text{r}}^2}{c^2} A^T(\theta_{\text{out}}, \omega_{\text{out}}) \mathcal{P}^i, \quad (2)$$

where A^T is the transpose of A . Finally, we obtain that the intensity of the appropriate Raman band, I_i , is given by

$$I_i \propto \sum_{k \in \{111\}} |e^{\text{out}} A^T(\theta_{\text{out}}^k, \omega_{\text{out}}) \alpha^i A(\theta_{\text{in}}^k, \omega_{\text{in}}) e^{\text{in}}|^2, \quad (3)$$

where the summation is taken over four different possible orientations of the {111}-platelets in the lattice. Here, e^{in} and e^{out} are polarization vectors of

Fig. 2. Calculated depolarization ratio, $\Delta_{[1 0 0]}$, of the Si-H (2100 cm^{-1}) and H_2 (4160 cm^{-1}) Raman signals. Dotted line shows the dielectric constant of Si at 488 nm.

the incident and scattered light, respectively. In case of H_2 , Eq. (3) is averaged over all possible orientations of the principal axes of α^{H_2} with respect to the labor frame, whereas for the 2100-cm^{-1} band we assume that the Si-H bonds are aligned along the platelet normal.

$\Delta_{[1 0 0]}$ calculated from Eq. (3) for the 2100- and 4160-cm^{-1} bands as a function of ϵ is shown in Fig. 2. In our calculations we assumed that the Raman tensor of H_2 is the same as that of the free molecule [9], $\delta^{\text{H}_2} = 0.66$, whereas for the 2100-cm^{-1} band we used the value of the Si-H bond anisotropy $\delta^{\text{Si-H}} = 0.35$, obtained from the Raman study of vacancy-hydrogen complexes in Si [11].

It follows from Fig. 2 that the polarization properties of the 2100- and 4160-cm^{-1} bands derived from Fig. 1 ($\Delta_{[1 0 0]} \cong 1$) are explained very well by the model of the platelet with ϵ well below than that of Si. This is what one should expect for the $[\text{2Si-H}]_n$ platelets. Indeed, this model assumes that $[\text{2Si-H}]_n$ is an open structure comprising two hydrogenated Si(111) layers with H_2 trapped in between.

We also studied the dependency of $\Delta_{[1 0 0]}$ on the sample temperature during the plasma treatment. Fig. 3 shows the integrated intensities and $\Delta_{[1 0 0]}$ of the 2100- and 4160-cm^{-1} bands as a function of the sample temperature. As one can see, $\Delta_{[1 0 0]}$ of the H_2 signal remains constant, whereas at 50°C $\Delta_{[1 0 0]}$ of the 2100-cm^{-1} band is ≈ 0.5 . As the temperature rises, the 4160-cm^{-1} band grows up and when it reaches the maximal intensity, the 2100-cm^{-1} band becomes nearly depolarized. We interpret this transition as a change of the platelet from the optical dense structure without H_2 ($[\text{H}_2^*]_n^{\text{D}}$) to the $[\text{2Si-H}]_n$ structure accompanied by the formation of H_2 molecules in the interstitial region of the platelet. Indeed, according to Fig. 2, $\Delta_{[1 0 0]} = 0.5$ for the 2100-cm^{-1} band corresponds to $\epsilon = 14$, which is rather close to the dielectric constant of Si.

We believe that a double layer of $[\text{H}_2^*]_n^{\text{D}}$ is the most plausible candidate for the structure with $\epsilon = 14$.

Fig. 3. Dependence of sample temperature during hydrogen plasma treatment on the integrated intensities (top figure) and on the depolarization ratio, $\Delta_{[1 0 0]}$, (bottom figure) of the Si-H (2100 cm^{-1}) and H_2 (4160 cm^{-1}) Raman signals. Note that the intensity of the Raman signal of H_2 was scaled up by factor of 7.

Apparently, of all proposed models for the {111}-platelets only this one is expected to have the highest value of ϵ due to the layer of Si atoms located it between the Si(111) surfaces [4]. This picture is in agreement with calculations of Kim and Chang [5], who found that $[\text{H}_2^*]_n^{\text{D}}$ has the lowest formation energy at small lattice dilations. When the lattice dilates the $[\text{H}_2^*]_n^{\text{D}}$ structure recrystallizes to $[\text{2Si-H}]_n$ accompanied by the formation of H_2 in the two Si(111) planes. This transformation occurs at 100°C , as seen from Fig. 3.

4. Summary

In summary, we presented a detailed analysis of the polarized Raman scattering spectra from the {111} hydrogen-induced platelets in silicon, which were hydrogenated by remote plasma exposure. Our analysis identifies two different structures, which exist simultaneously with concentrations depending on the plasma conditions.

Quadruplevoids in amorphous Si:H

Thomas Krüger*, Alexander F. Sax

Institut für Chemie, Karl-Franzens-Universität Graz, Strassoldogasse 10, A-8010 Graz, Austria

Abstract

The mechanism of the Staebler–Wronski effect is still in question. We assume that a defect precursor A is transformed into the actual, metastable defect B by excitation and subsequent electron trapping. Calculations on two large, distorted silicon clusters are presented which contain a bent and a pyramidal void, respectively, created by removal of four adjacent silicon atoms. A QM/QM embedding procedure is employed using a density functional (BP86) and a semiempirical method (AM1). Full geometry optimization results in novel and unprecedented structure information. Excitation energies and electron attachment energies are presented. These findings substantiate the new ideas regarding the nature of A and B. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Staebler–Wronski effect; Amorphous Si:H; Microvoids; Embedding calculations

1. Introduction

In various applications amorphous hydrogenated silicon (a-Si:H) could serve as a cheap and technically more versatile replacement for crystalline silicon (c-Si). Unfortunately, however, the practical use of a-Si:H is limited by the well-known Staebler–Wronski effect (SWE) [1,2].

Despite a vast amount of experimental information its mechanism is still discussed controversially (see Ref. [3]). It is known that a-Si:H is interspersed with an enormous amount of microvoids. Assuming a spherical structure the mean void radius amounts to 3.3–4.3 Å [4–6]. It is plausible that certain sites of the inner void surfaces act as the (neutral) precursors (A) of the light-induced dangling bonds B.

We assume that the exposure of neutral A to sunlight enables A to trap an electron from the conduction band. By relaxation of this intermediate the metastable dangling bond B is formed. This assumption is corroborated by recent work indicating that the majority of light-induced defects is *negatively* charged [7]. The thermal reformation of A (the annealing

process) may be considered the reverse of the photo-electronic formation of B and will finally lead to electron-hole-recombination.

In order to substantiate the mechanistic concept mentioned above we have to obtain knowledge about the geometric and electronic structure of the voids' localized states as well as about the corresponding excitation and electron attachment energies. Results regarding voids from one to three adjacent Si atoms missing are given in a previous paper [3]. In the present article we will show the results of calculations on *quadruplevoids* (tetravoids).

2. Strategy and methods

The methods of theoretical chemistry result in *local* information about a system, and this is what we need to have. We use the following approach explained in detail in Ref. [3]: the system of interest is partitioned into two parts, where the more interesting part (the core) is treated at a higher level of theory, and the rest of the system (the bulk) is described by an approximate and computationally less demanding method. During the calculations the outer sphere of the core is saturated by H atoms (the link atoms). The embedding of the core into the bulk, i.e. the *coupling* of the two parts, is

*Corresponding author. Fax: +43-316-380-9893.

E-mail address: thomas.krueger@kfunigraz.ac.at (T. Krüger).

performed using the ONIOM scheme [8] which is implemented in the Gaussian98 program package [9]. To calculate the core we employ the combination of Becke's 1988 exchange [10] and Perdew's 1986 correlation functional [11] (BP86) together with the 6-31G* standard basis set. The bulk is treated by means of the semiempirical method AM1 [12,13]. The vertical excitation energies are calculated by use of the single-excitation CI method [14] based on the corresponding Hartree–Fock orbitals. All energy values given refer to the core plus link atoms only.

The material is modeled by the cluster $\text{Si}_{139}\text{H}_{116}$, an approximately spherical entity of T_d symmetry with a diameter of about 17 Å which is derived from a clipping of c-Si where the outer surfaces are hydrogenated. Four adjacent silicon atoms are removed from the center of the cluster, and the neighboring atoms are regarded as the core of the system. Then we allow for *total* geometry relaxation.

One could object that an investigation of voids in this cluster does not allow for statements regarding *amorphous* silicon, because its structure is derived from *crystalline* Si. However, during relaxation more or less severe distortions of the ideal lattice occur. The distance matrices of the *final* structures have been evaluated statistically to obtain distance histograms. These histograms show the typical features of the radial distribution function of an amorphous material.

The work of other authors regarding vacancies in silicon is appreciated in Ref. [3].

3. Results

If four adjacent Si atoms have to be removed, three arrangements are possible: either a *linear* (zigzag) or a *bent* or a *pyramidal* quadruplevoid will emerge. Since the linear arrangement is similar to the triplevoid already treated in the previous paper, we will concentrate on the bent and on the pyramidal quadruplevoid.

3.1. The bent quadruplevoid

Locally the bent quadruplevoid shows up C_2 symmetry. The overall symmetry of the whole system, however, is C_1 only. The core consists of the 10 atoms surrounding the void and two additional atoms belonging to the next sphere. This is necessary because we have to avoid situations where one bulk atom is bound to two core atoms so that linking the inner and outer part would become difficult (see Ref. [15]).

At the beginning of the geometry optimization (relaxation) 10 unpaired electrons (dangling bonds) are present. Eight of the corresponding Si atoms have a next-neighbor distance of 3.82 Å, whereas the remaining two are connected already by a Si–Si single bond. It is to

be expected that the system will try to overcome this situation by rearranging its atoms so that new bonds are formed. Fig. 1 shows the result of the process where the gray circles denote the original positions of the four atoms removed. The core atoms have moved towards one another in pairs, preserving the bent structure of the void. Five new bonds are created: four single bonds and one double bond connecting the two Si atoms which have already been bound. Note that the newly formed bonds are stretched by not more than 8% vs. the typical bond lengths in the unperturbed cluster. Considerably strained bonds (+30% vs. standard) which are sometimes discussed in the context of the SWE are not found at all.

The lowest excited singlet state of the core is located 1.43 eV above the ground state which fits very well into the band gap of a-Si:H. The transition is of HOMO→LUMO type where both orbitals are localized at the double bond. However, the oscillator strength of this transition amounts to $f = 0.024$ only, thereby indicating that the transition is very improbable to occur. There is no other excited state within the energy range relevant for the SWE.

This can be explained as follows: the most simple molecule possessing a Si–Si double bond is disilene (Si_2H_4). The HOMO→LUMO excitation requires a quite high energy of 4.25 eV, but this transition is allowed because of the high oscillator strength ($f = 0.656$). If, however, the four H atoms are positioned so that the surrounding of this double bond is equivalent to the highly distorted surrounding of the double bond in the bent void, then the excitation energy drops to 1.65 eV but also the oscillator strength decreases significantly ($f = 0.062$). This can be attributed to the fact that HOMO and LUMO partly lose their explicit bonding and antibonding character, respectively, because of the increased mixing with other orbitals.

Fig. 1. Optimized structure of the bent quadruplevoid in $\text{Si}_{139}\text{H}_{116}$.

We assume that the primary step of the SWE is the trapping of a conduction band electron by an excited state of A. So B must be an anion (more precisely: the anionic part of a zwitterion [3]) if A is a neutral closed-shell system, i.e., A must be able to stabilize a negative charge. In case of the bent quadruplevoid the vertical electron attachment energy $E_{A,v}$ amounts to 2.77 eV. The excess electron is trapped at the double bond yielding $^{-}\text{Si-Si}^{\bullet}$.

3.2. The pyramidal quadruplevoid

As with the bent void 10 unpaired electrons are present at the beginning of the geometry optimization. The corresponding atoms belong to three different layers of the silicon lattice. The atom above the top of the pyramid, labeled “1” in Fig. 2, which is the only atom belonging to layer 1, is quite isolated from the next six radical centers in layer 2 (distance = 4.48 Å). The three atoms below the base of the pyramid belong to layer 3. The core consists of said 10 atoms in local C_3 symmetry and nine further Si atoms which had to be included due to the reason explained in the last section. The overall symmetry of the cluster is C_s .

The shape of the pyramidal void is much more spherical than the shape of the bent void. In consequence, to form five new bonds would require a much larger distortion of the bulk. So it seems possible that some of the unpaired electrons will stay unpaired. Fig. 2 shows the result of the optimization. Three new single bonds have been generated in layer 2 giving rise to a nine-membered ring. However, atom 1 remains isolated. In layer 3 the Si-Si distances become shorter by about 0.06 Å, but no double bonds are formed. Instead the originally three radical centers retain their character so that the electronic ground state of the pyramidal quadruplevoid is that of a fourfold singlet radical. Note that also this system does not possess any significantly elongated bonds.

Fig. 2. Optimized structure of the pyramidal quadruplevoid in $\text{Si}_{139}\text{H}_{116}$. The void atoms occupy the corners of the polygons.

It is easy to reconstruct that atom 1 has not been incorporated into the system of the other atoms due to the strain exerted by the bulk. But what is about the three atoms belonging to layer 3? At the beginning of the optimization they are arranged in C_{3v} symmetry. So the three unpaired electrons occupy one totally symmetric orbital (a_1) and a pair of energetically higher but degenerate orbitals of e type. This situation gives rise to a Jahn–Teller distortion. Two of the three radical centers, labeled “3” and “6”, respectively, in Fig. 2, get closer to each other as far as it is admitted by the strain of the other atoms, and the two electrons occupy an energetically lower bonding orbital. The remaining center (“10”) is pushed to the left. The two unpaired electrons of 1 and 10 couple weakly yielding the core’s HOMO as the *antibonding* combination of the respective atom orbitals, whereas the *bonding* analogue (LUMO) is shifted to higher energies.

The HOMO→LUMO transition needs an energy of 1.46 eV, but, in contrast to the situation with the bent quadruplevoid, it is highly probable due to an oscillator strength of $f = 0.622$.

The stabilization energy of an excess electron amounts to the remarkable value of 3.32 eV. Negative charge and spin density are delocalized over atoms 1 and 10.

4. Summary and outlook

In continuation of previous work [3] we have investigated quadruplevoids which could play a role in the mechanistic description of the SWE. They are generated by removing four adjacent Si atoms in the center of a hydrogenated Si-cluster. Then the total systems are allowed to relax energetically. In this process they try to repair the unfavorable starting configuration, but the tendency of the core to form new bonds is hindered partially by the bulk’s strain exerted on the core. *If* slightly stretched bonds can be generated, it will happen. *If*, however, the necessary rearrangement of bulk atoms would be too extensive, *then* the system reconciles itself to the existence of weakly coupled radical centers. Significantly stretched bonds have not been observed.

In contrast to its bent analogue the *pyramidal* quadruplevoid shows up a $S_0 \rightarrow S_1$ -transition which is both energetically favorable and electric dipole allowed. Moreover, this void is able to stabilize an excess electron by an energy as high as 3.32 eV. So it represents a structural entity in a-Si:H which meets the expectations regarding the metastable defect B and its precursor A.

Abstract

The interaction of hydrogen impurity with radiation defects in silicon is studied by DLTS. Prior to the electron irradiation at room temperature, hydrogen was introduced into the p-type samples by wet chemical etching. Two new deep-level centers are detected only in float-zone crystals. The depth profiles of the new centers resemble those of the boron–hydrogen pairs. One center reveals a charge-driven bistability; the deep levels corresponding to both of its configurations as well as transformation kinetics are determined. Our results indicate that the bistable defect is interstitial in nature and includes boron and hydrogen. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Radiation defects; Bistability

1. Introduction

The dominant defects, which are created by room temperature electron irradiation, are mostly complexes of primary radiation defects with impurities like oxygen, carbon or shallow level dopants. Recently, hydrogen was also discussed as a common and, under certain conditions, an abundant impurity in silicon. The interaction of hydrogen with radiation defects in silicon has been studied for many years. Usually, hydrogen is introduced into the samples by chemical etching or plasma treatment *after* the irradiation with high energetic particles [1–4], when formation of the radiation-induced defect spectrum has already been completed. The hydrogen treatment after the irradiation process excludes the interaction of hydrogen with mobile radiation-induced species, such as vacancies and self-interstitials, which are not stable at room temperature. Another approach to investigate the hydrogen/radiation defect interaction is proton implantation, which simultaneously generates the intrinsic point defects and introduces the hydrogen atoms. Indeed, new hydrogen-related complexes [5,6], which are not observed using the

post-hydrogenation, have been revealed in this way. However, due to the simultaneous migration of hydrogen, vacancies, and interstitials, the formation process of stable defects is complicated and difficult to follow in detail. The situation can be simplified if silicon crystals are hydrogenated *before* irradiation. Several IR absorption and DLTS studies already showed that hydrogen-related complexes are formed by room temperature electron irradiation following pre-hydrogenation during growth or high-temperature treatment in hydrogen-containing atmosphere [7,8]. However, interpretation of the results is not straightforward because the state of hydrogen after high-temperature saturation is not fully understood. The purpose of the present work is to study the formation of radiation-induced defects in hydrogenated samples, where virtually all hydrogen atoms are bound in boron–hydrogen pairs before the electron irradiation.

2. Experimental

Boron-doped ($[B] = (0.8\text{--}2.5) \times 10^{15} \text{ cm}^{-3}$, Cz or FZ) silicon wafers were hydrogenated by chemical etching in HF:HNO₃ acid mixtures at ambient temperature. After Schottky diode preparation, the reverse-bias annealing

E-mail address: nay@ipmt-hpm.ac.ru (N. Yarykin).

(RBA) procedure was applied to move hydrogen deeper in the crystals and to form well-defined profile of boron–hydrogen pairs [9]. A few samples were hydrogenated by H-plasma treatment at 100°C. The final hydrogen distribution was monitored by CV measurements. Hydrogenation did not introduce any deep-level centers in measurable concentration. The hydrogenated diodes were subjected to 1.5 or 6 MeV electron irradiation with a fluence of $(0.3\text{--}1.0) \times 10^{15} \text{ cm}^{-2}$ at nominal room temperature.

The measurements were performed on a computerized DLTS system with lock-in sine-wave correlation; the rate window was set in the range between 0.5 and 120 s^{-1} . The curves were taken during heating with rates of $3\text{--}9 \text{ K s}^{-1}$. Spatial distribution of the deep-level centers was calculated by digital differentiation of the DLTS signal dependence on the filling pulse amplitude at a fixed reverse bias. The inhomogeneous profile of shallow dopants, which was determined from the CV measurements, was properly included in the evaluation of the deep-level defect concentrations. The MCTS curves were measured using minority-carrier injection from an LED through the semitransparent Schottky contact.

3. Results

The DLTS spectrum after high-energy electron irradiation of the hydrogenated FZ sample is shown in Fig. 1. The DLTS parameters were set to monitor only the defects in the hydrogenated region. The dominant features of the majority-carrier trap spectrum (Fig. 1b) are the donor levels of the divacancy (V_2), interstitial carbon (C_i), and two overlapping peaks labeled MH3-B and H3, respectively. The MH3-B level appears in the spectrum only after cooling the sample from room temperature under reverse bias, indicating a charge-driven bistability of the center. However, no new deep level emerges in the lower half of the gap instead of MH3-B after zero-bias cooling. Therefore, the MCTS technique has been applied to monitor the defect levels in the upper half of the gap. The MCTS spectrum shown in Fig. 1(a) exhibits an electron trap (labeled MH3-A) with a metastable behavior complementary to that of MH3-B. Detailed measurements verify that the kinetics of the MH3-A center formation during zero-bias annealing in the temperature range from 195 to 215 K, is the same as the kinetics of the MH3-B center disappearance. Both levels disappear in our samples after several hours at 360 K. Thus, we conclude that the MH3-A and MH3-B levels belong to two different configurations of the MH3 bistable center. The MH3 and H3 defects are not detected after electron irradiation of pre-hydrogenated Cz-Si samples.

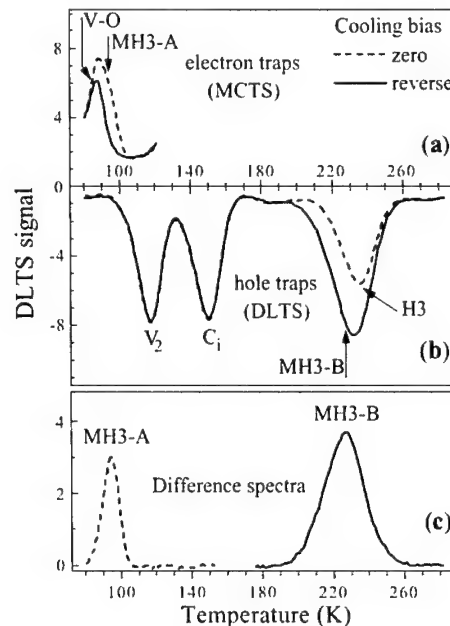

Fig. 1. MCTS (a) and DLTS (b) curves measured after cooling under different conditions for the pre-hydrogenated p-type FZ-Si irradiated with $7 \times 10^{14} \text{ cm}^{-2}$ of 6 MeV electrons, and the difference spectra (c) calculated by subtracting the curves in panels (a, b). The rate window is 52 s^{-1} for both DLTS and MCTS curves.

The energy of the observed levels was determined by measurements of the peak temperature positions at different correlator rate windows. Both MH3-A and MH3-B peaks strongly overlap with signals from other defects, and their correct positions can be determined only from the difference spectrum calculated by subtraction of the curves measured after zero- and reverse-bias cooling, see Fig. 1(c). The H3 peak maximum was determined after zero-bias cooling, when there was no perturbation from the MH3-B peak contribution. The energies for hole emission for the MH3-B and H3 levels were determined to be 0.44 and 0.51 eV, respectively. Only a rough estimate of $E_c - 0.22 \pm 0.04 \text{ eV}$ can be given for the MH3-A energy position, due to the liquid nitrogen cooling of the MCTS setup.

The depth distributions of the deep-level centers observed in FZ-Si are shown in Fig. 2 along with the net boron profile. The MH3 and H3 centers are strongly localized in the region around $1.8 \mu\text{m}$ from the surface, where 50% of boron is passivated during RBA before irradiation. The divacancies exhibit a rather flat profile. We have varied the concentration and depth distribution of boron–hydrogen pairs by performing the RBA treatment at different temperatures and voltages. In some samples, hydrogen has also been redistributed after chemical etching by furnace annealing without

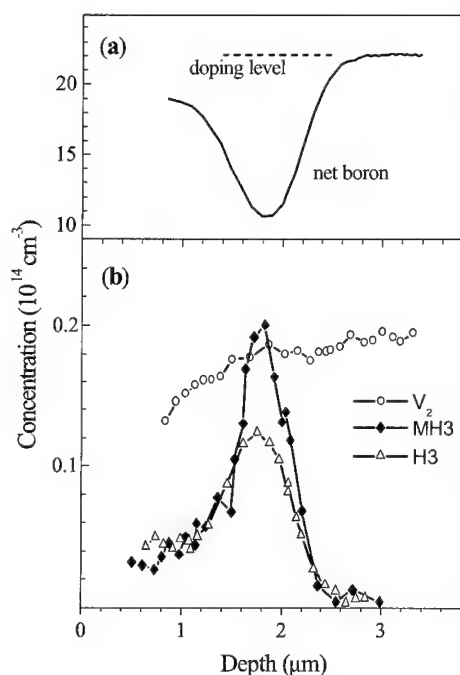

Fig. 2. The depth profiles of the boron acceptors (a) and the deep-level centers (b) formed in p-type FZ-Si after RBA hydrogenation and subsequent irradiation with the $5 \times 10^{14} \text{ cm}^{-2}$ fluence of 1.5 MeV electrons. The MH3 center concentration was measured in the B-configuration.

Schottky diodes. In all studied cases, the shape of the depth profiles of the MH3 and H3 centers resembles those of boron–hydrogen pairs. Thus, we conclude that the MH3 and H3 centers are hydrogen-related radiation defects.

4. Discussion

DLTS levels very similar to MH3-B and H3 have recently been found in epitaxially grown silicon after irradiation with α -particles [10]. The energies for hole emission for the $\text{H}\alpha_1$ and $\text{H}\alpha_2$ levels [10] as well as the transformation kinetics of the bistable $\text{H}\alpha_2$ match closely our values for H3 and MH3-B, respectively. The very similar energies give strong evidence to the identical nature of the defects observed in different crystals. Apparently, the samples used in Ref. [10] were contaminated with hydrogen during growth or diode preparation.

The MH3 and H3 centers have a number of similar features, but the MH3 centers have only been detected in pre-hydrogenated samples, while the H3 defects can also be formed by hydrogenation *after* irradiation (for more data on H3, see Ref. [11]). Taking also into account that

the MH3 center concentration follows the distribution of boron–hydrogen pairs, we conclude that the MH3 center forms by the capture of a mobile radiation-induced defect to the boron–hydrogen complex. The mobile defects formed at the highest concentrations in p-type silicon are known to be vacancies, self-interstitials, and their products, boron and carbon interstitials. The latter can be excluded from the following consideration because (i) C_i is immobile during electron irradiation at room temperature and (ii) C_i migration at 340 K results in no changes in the MH3 center concentration. Vacancies are also not likely to be involved in the MH3 formation since the divacancy depth profile (being comparable in concentration) remains essentially flat around the pile-up of the MH3 defects (Fig. 2). On the other hand, self- and boron-interstitials may be trapped by the $\text{B}_s\text{-H}$ pairs forming $\text{B}_i\text{-H}$ and $\text{B}_i\text{-B}_s\text{-H}$ complexes, respectively. Of the two possibilities, the latter gives a simple explanation for the absence of the MH3 centers in oxygen-rich Cz-Si. Indeed, the creation of the $\text{B}_i\text{-B}_s\text{-H}$ complex should be strongly suppressed in Cz material as most of boron interstitials are consumed by oxygen forming the B_iO_i complexes [12].

5. Conclusion

We have investigated the DLTS spectrum of stable radiation defects formed in p-type silicon which was hydrogenated by wet chemical etching and annealed at 340–430 K before the irradiation. The pre-hydrogenation of FZ-Si results in the appearance of two additional MH3 and H3 centers immediately after irradiation at room temperature. The defect depth profiles correspond to the distribution of boron–hydrogen pairs and, in the case when approximately 50% of boron have been converted to the $\text{B}_s\text{-H}$ pairs, the defect concentration is comparable with that of divacancies. The MH3 defect exhibits a charge-driven bistability with characteristic transformation temperatures about 200 and 260 K for the bias-off and bias-on conditions, respectively. The bistable center anneals out at 360–380 K, while the concentration of the H3 center increases during such annealing. The MH3 and H3 defects are not detected in Cz-Si. Analysis of the results allows us to tentatively ascribe the MH3 and H3 centers to interstitial complexes including hydrogen and boron.

Abstract

We report a systematic investigation on the Fermi-level dependence of the formation of two different types of hydrogen molecules in silicon. Hydrogen molecule at the tetrahedral (T) site ($H_2(T)$) is formed only in heavily doped n-type below 200°C, but is observed both in the n- and p-type above 200°C. The temperature dependence is due to the increase of the thermally activated carrier concentration. The possible precursors of the $H_2(T)$ are $H^+(BC)$ and $H^0(BC)$ in the p-type, and $H^-(T)$ and H^0 in the n-type. The Fermi level dependence of the formation of the hydrogen molecule trapped in platelets ($H_2(p)$) above 250°C is very different from that below 250°C. The result suggests that platelets are formed from hydrogen-complexes other than the H_2^* above 250°C. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Hydrogen molecule; Crystalline silicon; Fermi level

Among a number of different configurations of hydrogen in semiconductor, molecular hydrogen (H_2) has been attracting an increasing attention especially since the first experimental confirmation of its existence in silicon (Si), in 1996 [1,2]. The H_2 in the Si is chemically inactive and predicted by many theoretical calculations to be very low in energy [3–5]. Recent vibrational spectroscopic studies revealed at least two types of the H_2 in crystalline Si after exposure to hydrogen plasma. The two H_2 have different vibrational frequencies corresponding to the different sizes of their trapping sites and accordingly the different strengths of interaction with their surroundings. The vibrational line at 4158 cm^{-1} has been attributed to the H_2 trapped in platelets [6], i.e., planar defects of diameters up to 100 nm, while that at 3605 cm^{-1} to the H_2 at the tetrahedral (T) interstitial site [7–9]. The intensities of the two H_2 depended strongly upon the substrate type

and the temperature during hydrogenation [10]. In the present study, we report a systematic study on the Fermi-level dependences of the formation of the H_2 in the Si. The Fermi-level position is controlled by doping P or B atoms in the Si over a wide range. Changing the Fermi-level position with respect to the band gap is expected to cast light upon the formation mechanisms of hydrogen molecules, since it would affect the stable configuration of atomic hydrogen in the Si [3–5].

Float zone (FZ) p-type Si wafers with a resistivity of $> 50\ \Omega\text{ cm}$ were used as silicon substrate. In order to obtain n- and p-type Si samples, 50 keV P^+ and 30 keV B^+ ions were implanted in the FZ Si wafers at various fluences ranging from 1×10^{12} to $1 \times 10^{15}\text{ P}^+/\text{cm}^2$ and from 1×10^{12} to $1 \times 10^{15}\text{ B}^+/\text{cm}^2$, respectively. The ion energies were selected to cover the optical penetration depth of the visible light used in the Raman scattering measurements. The implanted samples were annealed at 900°C for 30 min in an atmosphere of flowing N_2 gas to activate the implanted dopants and annihilate other defects. The resulting dopant

E-mail address: ishioka.kunie@nims.go.jp (K. Ishioka).

concentrations ranged from 1.6×10^{17} to 1.6×10^{20} P/cm³ and 1.0×10^{17} to 1.0×10^{20} B/cm³. The Fermi level E_{Fermi} of each Si sample was estimated from the concentration and the hydrogenation temperature [11], neglecting passivation of dopants by atomic hydrogen. All the Si samples were hydrogenated with atomic hydrogen in a remote downstream of hydrogen plasma for 30 min. The samples were placed in the quartz tube 60 cm apart from the plasma to suppress the damage by the activated species. The error bar in the substrate temperature during hydrogenation was $\pm 10^\circ\text{C}$ for different positions in the furnace. The details of the method and hydrogenation conditions have been reported elsewhere [12,13]. Raman scattering measurements were performed at room temperature using a 514.5 nm light as an excitation source. In the present study, all the Raman intensities were normalized by the intensity of the optical phonon of Si of the same sample measured under the same condition.

Fig. 1 shows the Raman spectra of the Si samples after hydrogenation for 30 min at a substrate temperature of 165°C . The weak, relatively narrow Raman line around 3600 cm^{-1} was assigned to the H_2 at the T sites ($\text{H}_2(\text{T})$) in the preceding infrared [7,8] and Raman [9] studies. At this hydrogenation temperature, $\text{H}_2(\text{T})$ was observed only for the n-type Si samples. The small peak around 3650 cm^{-1} is the O–H stretching of water in the air and decreases under N_2 purge. The broader Raman line around 4150 cm^{-1} , which was attributed to the H_2 trapped in the platelets ($\text{H}_2(\text{p})$) [6], was observed for all the samples except very heavily doped n-type Si. We also

observed Raman band due to the Si–H bonds terminating platelets (Si–H(p)) around 2100 cm^{-1} , whose intensity showed a good correlation with that of the $\text{H}_2(\text{p})$.

The formation of the hydrogen molecules is not determined solely by the Fermi-level position, but is also affected by the hydrogenation temperature. Fig. 2 shows the Raman spectra of the Si samples after hydrogenation at 305°C . The formation of the $\text{H}_2(\text{T})$ was maximum in n-type, but was also observed in the p-type. The $\text{H}_2(\text{p})$ intensity exhibited a maximum for a moderately doped p-type Si. It is noted that the intensities of the $\text{H}_2(\text{T})$ and $\text{H}_2(\text{p})$ exhibited an anti-correlation to each other after hydrogenation at 305°C . Fig. 3 summarizes their Raman intensities after hydrogenation at different temperatures as a function of the Fermi-level position.

In the present study, hydrogen is introduced as neutral H atoms into the Si samples. The energetically favorable position and charge state in the Si are determined by the position of the Fermi level. In many calculations, there is an agreement that H is stable at a bond-center (BC) site with a positive charge in the p-type and at a T site with a negative charge in the n-type [3–5,14–16]. However, the global minimum for neutral H (H^0) is still controversial. We interpret the suppression of the $\text{H}_2(\text{T})$ formation in p-type below 200°C to be due to the Coulomb repulsion between two H^+ (BC) and the lack of electrons to form interatomic bonds [5]. Above 200°C on the other hand, the intrinsic carrier concentration exceeds the acceptor concentration. The H^+ (BC) acts as a donor with an electronic state slightly below the conduction band minimum [4,16–18], then captures an electron and forms $\text{H}^0(\text{BC})$. The reaction

Fig. 1. The Raman spectra of the Si samples at different P and B doping concentrations after hydrogenation at 165°C for 30 min. The Raman lines around 2000 , 3600 and 4150 cm^{-1} are attributed to the SiH(p), $\text{H}_2(\text{T})$, and $\text{H}_2(\text{p})$, respectively. The vertical axis is normalized by the integrated Raman intensity of the optical phonon line of silicon.

Fig. 2. The Raman spectra of the Si samples at different P and B doping concentrations after hydrogenation at 305°C for 30 min. The vertical axis is normalized by the integrated Raman intensity of the optical phonon line of silicon.

Fig. 3. The integrated Raman intensities of the $H_2(T)$ and $H_2(p)$ in the Si samples after hydrogenation as a function of the Fermi-level position E_{Fermi} . The intensities are normalized by that of the optical phonon of silicon. E_{CBM} denotes the conduction band minimum.

$H^0(BC) + H^+(BC) \rightarrow H_2(T)$ is thus promoted thermally in p-type at high temperatures. The effective formation of the $H_2(T)$ in heavily doped n-type below 200°C suggests the absence of Coulomb repulsion, i.e., the coexistence of the $H^-(T)$ and H^0 . Since $H(T)$ has on a deep level in the middle of the band gap [16] or closer to the valence band maximum [4], the maximum of $H_2(T)$ formation near the conduction band minimum may be explained better by assuming that H^0 is at the BC than at T.

Our results on the Fermi-level dependence of the $H_2(p)$ formation was very different from that of the platelet concentration studied by transmission electron microscopy (TEM) [17,18], which was increased monotonically as the Fermi level approached the conduction band minimum. A possible reason for the large discrepancy is the different methods of the sample preparation. In the previous TEM work, the samples were hydrogenated sequentially at two different temperatures (150°C and 275°C) to nucleate platelets and extend them up to 100 nm size, respectively. We have confirmed that, for the hydrogenation temperature above 250°C, the formation of the $H_2(p)$ is remarkably enhanced when the sample is exposed to the H atoms at a lower temperature in advance [10]. The resemblance of the Fermi-level dependences of the $H_2(T)$ in the present study and the platelet concentration in the previous TEM work suggests a possibility that the $H_2(T)$ is transformed into platelets when the sample is hydrogenated again at a higher temperature. We have

confirmed the possibility by performing thermal annealing on an n-type sample in which considerable amount of $H_2(T)$ and very little $H_2(p)$ were observed. After furnace anneal at 55°C for 30 min, the Raman peak of $H_2(p)$ was increased significantly. With increasing annealing temperature, the intensities $H_2(T)$ and $H_2(p)$ were decreased and increased, respectively. The result may also explain the anti-correlation between the intensities of the $H_2(T)$ and that of the $H_2(p)$ at 305°C.

The $H_2(p)$ formation below 235°C was not significantly dependent on the Fermi level except for very heavily doped n-type, whereas it exhibited a rather complicated dependence on the Fermi level at 305°C. Since the $H_2(p)$ is stable up to 400°C, the temperature dependence may be due to the thermal stability of the precursors of platelets [19]. Theoretical calculations suggest that the diatomic complex H_2^* is a precursor of the $\{111\}$ platelets [20,21]. An infrared absorption study reported that H_2^* was annealed out below 250°C [22], being consistent with our observation on the temperature dependence of $H_2(p)$. On the other hand, the insensitiveness of $H_2(p)$ intensity to the Fermi level is very different from the theoretically predicted Fermi-level dependence of H_2^* , and leaves room other precursors. The Fermi-level dependence for 305°C hydrogenation, which has a maximum when the Fermi level is in the mid-gap, suggests that $H^+(BC)$ and $H^0(T)$ are involved in the formation of platelets.

In conclusion, we observed a significant Fermi level and temperature dependences of the formation of the two different types of H_2 in hydrogenated crystalline Si. The $H_2(T)$ is formed mainly from H^0 and $H^-(T)$ in the n-type and from $H^0(BC)$ and $H^+(BC)$ in the p-type. The latter mechanism is activated thermally above 200°C. The temperature dependence of the $H_2(p)$ formation is consistent with the model in which the H_2^* is the precursor, whereas the Fermi-level dependence suggests the existence of other configurations of hydrogen as the precursors.

Defects agglomeration in the vicinity of hydrogen-related vacancy-type complexes in proton-implanted silicon

S.Zh. Tokmoldin*, B.N. Mukashev

Institute of Physics and Technology, Almaty 480082, Kazakhstan

Abstract

The results of IR studies of H interactions with radiation-induced defects in crystalline Si implanted with protons (Si:H) are presented. Wide doublets at ~ 1980 , 2060 and ~ 720 , 620 cm^{-1} with relatively low thermal stability (the doublets are fully annealed at 550 K) appear in IR absorption spectra of Si:H when implantation dose is increased. It is shown that the doublets may be assigned to nuclei of two hydrogenated amorphous phases with different densities. The Si:H stretching spectra of as-implanted samples are greatly simplified with the increasing implantation dose. Four groups of IR bands predominate at high implantation doses: 2222 cm^{-1} — VH_4 ; 2072 cm^{-1} — V_2H_2 ; the doublet at 2166 , 2191 cm^{-1} — V_2H_6 ; 1967 cm^{-1} —an interstitial-type complex and the doublet at 2107 , 2122 cm^{-1} —a vacancy-type complex. It is shown that the doublet at 2107 , 2122 cm^{-1} may be tentatively assigned to V_6H_{12} which can serve as nuclei or precursors of the $\{111\}$ platelets. © 2001 Elsevier Science B.V. Keywords: Silicon; Hydrogen; Vacancies; Platelets

1. Introduction

A lot of IR-active H-related defects were discovered in crystalline Si:H hydrogenated in different ways [1]. Intensive investigations using co-doping with H and D, uniaxial stress and impurity effect were not successful in unambiguously discriminating between hydrogenated vacancy- and interstitial-type complexes [2–5].

Earlier [6] we discovered correlated step function behavior of temperature dependence of anharmonicity between Si–H stretching lines lying above and below 2000 cm^{-1} . Detailed investigations [7–11] revealed that anharmonicity representing the Si–H dipole coupling to a defect host is sensitive to hybridization character and coordination of Si atom bonded to H that enables to make two most important conclusions:

1. Si–H stretching and bending lines may be separated into two different groups. Lines in the 2000 – 2250 and 550 – 700 cm^{-1} ranges are characteristic of vacancy-type complexes while lines in the 1900 – 2000 and 700 –

800 cm^{-1} ranges are connected with interstitial-type complexes.

2. The analysis of various molecular configurations of H-related complexes allows us to conclude that local Si–H modes of large complexes are mainly determined by simple structural units such as hydrogenated vacancies (VH , VH_2 , VH_3) and $\langle 100 \rangle$ split Si-interstitialcies (IH , IH_2).

Using these findings we have identified Si–H lines related to vacancy- and interstitial-type defects [7–11]: 2223 and 634 cm^{-1} — VH_4 ; 2166 , 2191 and 610 , 668 cm^{-1} — V_2H_6 ; 2072 and 610 cm^{-1} — V_2H_2 consisting of two VH structural units in $\text{VH} \oplus \text{VH}$ configuration; 2107 , 2122 and 588 , 610 , 694 cm^{-1} —a complex consisting of several VH_2 units in $\text{VH}_2 \oplus \text{VH}_2 \oplus \dots \oplus \text{VH}_2$ configuration; 1957 , 1967 and 718 , 750 cm^{-1} — $\{110\}$ interstitial chains consisting of two (or more) $\langle 100 \rangle$ -oriented IH and IH_2 structural units. All these assignments were confirmed in other works both theoretically [12–14] and experimentally [4,5,15].

In this paper, we study dose dependence of IR spectra of Si:H implanted with high-energy protons. We use the above-mentioned findings to consider an “amorphous”

background IR spectrum of Si:H and the behavior of local IR lines associated with vacancy-type complexes as well as of the $1.8\ \mu$ band [16] related to V_2 .

2. Experimental details

High-purity Si crystals ($N_B < 10^{14}\ \text{cm}^{-3}$, $N_{0,C} < 10^{15}\ \text{cm}^{-3}$) were implanted near 300 K with 7 and 30 MeV protons up to doses of $10^{18}\ \text{ion/cm}^2$. The samples were heat treated for 15 min in the range of 125–650°C with the step 25°C. IR spectra of Si:H were measured at 80 and 300 K with the resolution of $0.5\text{--}4\ \text{cm}^{-1}$ in the $400\text{--}10000\ \text{cm}^{-1}$ spectral range.

3. “Amorphous” background in the Si:H spectra

Wide doublets at ~ 1980 , $2060\ \text{cm}^{-1}$ and ~ 720 , $620\ \text{cm}^{-1}$ (shown by dashed line in Fig. 1) appear in IR spectra of Si:H with the implantation dose. The doublets may be considered as an “amorphous” background of Si–H local vibrational spectra. They have relatively low thermal stability and are fully annealed at about 550 K. No direct correlation of the “amorphous” background annealing with changes in Si–H spectrum was found.

It is known [17] that H atoms in plasma-deposited a-Si:H may be bonded in SiH_1 , SiH_2 and SiH_3 configurations. The ratio between SiH_1 , SiH_2 and SiH_3 strongly depends on the growth conditions, the most qualitative a-Si:H consists of mainly SiH_1 -radicals with stretching and bending modes at $\sim 1990\ \text{cm}^{-1}$ and $\sim 630\text{--}640\ \text{cm}^{-1}$. It was found [18] that the Si–H

stretching band is monotonously displaced to $\sim 2060\ \text{cm}^{-1}$ with decreasing a-Si:H deposition temperature. This effect was explained by the SiH_1 bonds coordination which becomes close to tetrahedral.

The Si:H “amorphous” background is close to the SiH_1 stretching bands in a-Si:H spectrum while in bending range it includes the second component at $720\ \text{cm}^{-1}$ and differs from a-Si:H spectrum. Taking into account the low thermal stability, the Si:H “amorphous” background may be associated with intermediate phases precursor to a-Si:H: groups at ~ 1980 , $720\ \text{cm}^{-1}$ and ~ 2060 , $620\ \text{cm}^{-1}$ may be assigned to SiH_1 -radicals in the vicinity of “amorphous” agglomerations of intrinsic interstitials and vacancies, respectively.

The “amorphous” agglomerations of H with intrinsic interstitials and vacancies may be considered as two different α_i - and α_v -phases. Since the $\sim 720\ \text{cm}^{-1}$ component is not observed in a-Si:H spectrum the α_i -phase differs from a-Si:H. Indeed, the density of agglomerations of intrinsic interstitial atoms in Si should be higher than the density of a matrix, while the density of a-Si:H prepared by H implantation [19] is lower than the density of Si. At the same time, IR spectrum of the α_v -phase is close to SiH_1 modes in a-Si:H obtained at low deposition temperatures [18] when the coordination of bonds is close to tetrahedral.

4. Dose behavior of point vacancy-type defects in Si:H

At low implantation doses the Si:H IR spectra contain a lot of Si–H lines as well as broad absorption bands due to electronic transitions of V_2 . Si–H spectrum is considerably simplified with implantation dose increasing and lines related to vacancy-type complexes such as VH_4 , V_2H_6 , etc. predominate.

Fig. 2 shows dose dependence of vacancy-type complexes and V_2 . The defects concentrations are saturated at a dose of $8 \times 10^{17}\ \text{H}^+/\text{cm}^2$ and then begin to decrease, the V_2 removal is very abrupt. The “amorphous” background absorption related to α_i - and α_v -phases simultaneously grows. At the same time a group of relatively low-intensity Si–H lines in the $2100\text{--}2150\ \text{cm}^{-1}$ range is simplified and doublet lines at 2107 , $2122\ \text{cm}^{-1}$ (at 77 K, 2104 , $2120\ \text{cm}^{-1}$ at 300 K) appear and grow, this process correlates with the V_2 abrupt removal.

The data show that point H-related complexes are formed at initial implantation stage when concentrations of the α_i - and α_v -nuclei are low. These complexes effectively trap H atoms up to the saturation of all dangling bonds and are stabilized outside the α_i - and α_v -nuclei. At the following implantation stage point defects migrate to “amorphous” nuclei and are trapped there. At large implantation doses the α_i - and α_v -nuclei capture point complexes and join with the formation of a-Si:H.

Fig. 1. An “amorphous” background in Si:H spectra. The background appears after 30 MeV proton implantation through aluminum foils at doses above $10^{17}\ \text{H}^+/\text{cm}^2$.

Fig. 2. Dose dependence of main IR lines in the spectra of crystalline Si implanted with 7 MeV protons at near room temperature.

These conclusions are in a good agreement with the data of experiments on hydrogenated a-Si:H prepared by ion implantation [19], in which it was shown that the dose of Si amorphization considerably decreases if a sample was previously implanted by H.

At low implantation doses the 2072 cm^{-1} line related to V_2H_2 consisting of two VH structural units in $\text{VH} \oplus \text{VH}$ configuration is most intense in Si-H spectrum (Fig. 2). At higher doses the 2072 cm^{-1} line is removed and this may be explained by trapping of additional H with the transformation of V_2H_2 to V_2H_6 . Indeed, annealing of the 2072 cm^{-1} line at a temperature of $\sim 570\text{ K}$ directly correlates with growth of the $2166, 2191\text{ cm}^{-1}$ doublet lines associated with V_2H_6 .

It is seen from dose dependences (see Fig. 2) that VH_4 forms before V_2H_6 and has different behavior. Annealing characteristics of these two centers do not also correlate with each other. The 2222 cm^{-1} line and the $2166, 2191\text{ cm}^{-1}$ doublet lines related to VH_4 and V_2H_6 , respectively, as well as the $2107, 2122\text{ cm}^{-1}$ doublet lines associated with a complex consisting of VH_2 units in $\text{VH}_2 \oplus \text{VH}_2 \oplus \dots \oplus \text{VH}_2$ configuration [7–11] are the most intensive local Si-H lines at high doses and after annealing above 600 K . So dose dependencies and annealing characteristics of Si-H lines related to vacancy-type defects reveal [8] that predominating complexes in Si:H are complexes containing even number of H atoms such as $\text{VH}_4, \text{V}_2\text{H}_2, \text{V}_2\text{H}_6$, etc. Intermediate complexes containing odd number of H atoms have unpaired electron on dangling Si-bonds and are acceptors, therefore, the complexes effectively traps H atoms which are in the $\dot{\text{I}}^+$ state. In [10], we found that these acceptor-like complexes serve as compensating

Fig. 3. Hydrogenated hexavacancy in Si. This complex can serve as nuclei or precursors of the $\{111\}$ platelets observed in [22].

centers for shallow donors. Weak lines in the $2000\text{--}2200\text{ cm}^{-1}$ range related to VH, VH_2 and VH_3 structural units may be assigned to these complexes.

The V_2 dose dependence does not correlate with dependencies for VH_4 and V_2H_6 (Fig. 2). Very abrupt V_2 removal at high doses correlates only with growth of the $2107, 2122\text{ cm}^{-1}$ doublet lines and its mechanism may be connected either with the V_2 capture in the vicinity of the α_i - and α_v -nuclei or with H-enhanced agglomeration of V_2 into multivacancy complexes. In the first case, it is expected that the α_i -nuclei will be removed while the α_v -nuclei will grow. However, we did not observe a noticeable change of the Si-H “amorphous” background. In the second case, one can expect the formation of multivacancy complexes such as $\{110\}$ planar tetravacancy chain and non-planar pentavacancy [20] as well as ring hexavacancy [21], which has to be most stable vacancy-type defect in Si.

Hydrogenated tetravacancy consisting of two end VH_3 units and two central VH_2 units should have doublet Si-H stretching modes near $2166, 2191\text{ cm}^{-1}$ and $2107, 2122\text{ cm}^{-1}$ with about equal intensity of related IR lines. In case of pentavacancy one should observe doublet lines near $2166, 2191\text{ cm}^{-1}$ and $2107, 2122\text{ cm}^{-1}$ related to three VH_3 and one VH_2 units, respectively, as well as a single line near 2072 cm^{-1} connected with VH unit; the intensities ratio for doublets and single line should be $3:1:1$. However, we did not observe any group of Si-H IR lines correlating with vibrations of hydrogenated tetravacancy and pentavacancy.

The V_2 removal may be caused by H-enhanced V_2 agglomeration with the formation of V_6H_{12} consisting of six VH_2 units (Fig. 3) which may be identified with the

2107, 2122 cm⁻¹ doublet as we proposed in [10]. Annealing temperature of the 2107 and 2122 cm⁻¹ doublets (> 600°C) is high in comparison with most other IR bands. This correlates with thermal stability of hexavacancy [21].

Abstract

Hydrogen molecule has been observed in ion-implanted silicon and attributed to be trapped in a multi-vacancy ($H_2(MV)$). In order to clarify the structure of the multi-vacancy trap of $H_2(MV)$, we investigated correlation between thermal annealing of multi-vacancies and $H_2(MV)$. The results indicated that the main multi-vacancy trap is an H-terminated di-vacancy (V_2H_6) and that it is formed not only by ion-implantation, but also by transformation from larger multi-vacancy such as V_6 and V_{10} during hydrogenation. A broad Raman line observed at 2030 cm^{-1} may be attributed to the Si–H in the multi-vacancy trap. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Hydrogen molecule; Multi-vacancy; Annealing; Si–H

Hydrogen is an important impurity in semiconductors. It changes electrical properties by passivating dopants and terminating dangling bonds around defects [1]. Hydrogen molecule is chemically inactive, and has been observed by vibrational spectroscopies in silicon [2–4] and GaAs [5]. In silicon, three types of hydrogen molecules with different vibrational frequencies have been reported. The hydrogen molecules whose sharp Raman line appears at 3605 cm^{-1} was attributed to hydrogen molecule that is located at the tetrahedral (T) interstitial site of silicon lattice ($H_2(T)$) [6]. The broad Raman line at 4158 cm^{-1} is considered to be the hydrogen molecule trapped in a planar defect called platelet ($H_2(p)$) [4]. These two hydrogen molecules were observed in crystalline silicon after hydrogenation. On the other hand, the Raman line at 3822 cm^{-1} was observed in ion-implanted silicon and assigned as the hydrogen molecule trapped by multi-vacancies ($H_2(MV)$), because it was observed only in ion-implanted silicon [7,8]. A theoretical simulation indi-

cates that the vibration frequency of hydrogen molecule is affected significantly by the size of multi-vacancy, and is 3834 cm^{-1} for the hydrogen molecule trapped by a H-terminated di-vacancy (V_2H_6) [9]. According to the calculation, hydrogen molecule is not stable in V_2H_6 but at the nearest T site to it.

In ion-implanted silicon, single vacancies are unstable at room temperature and form various sizes of multi-vacancies such as di-vacancy (V_2) and four-vacancy (V_4) [10,11]. In our previous study, we performed detailed annealing experiments to study the stability of $H_2(MV)$ [12]. The observed annihilation of $H_2(MV)$ under thermal annealing was attributed to the diffusion of $H_2(MV)$ out of the multi-vacancy trap rather than the annihilation of the multi-vacancy itself, because $H_2(MV)$ was observed again when we re-hydrogenated the sample after thermal annealing. The activation energy of the thermal annihilation of $H_2(MV)$ was estimated to be 0.8 eV, and is interpreted to be the potential barrier for the hydrogen molecule to go out of the trap site to the neighboring T site. However, the structure of multi-vacancies has not been clear. In the present study, we investigated the thermal stability of the multi-vacancy trap itself, without H-termination.

For this purpose, we carry out thermal annealing on freshly ion-implanted silicon and then hydrogenate each sample in order to investigate the structure.

Floating zone (FZ) p-type silicon wafers with a resistivity of $> 50 \Omega \text{cm}$ were used as silicon substrates. To obtain silicon samples with multi-vacancies, 200 keV Si^+ were implanted in the FZ silicon wafer at a fluence of $2 \times 10^{14} \text{Si}^+/\text{cm}^2$. This fluence leads to an effective formation of $\text{H}_2(\text{MV})$ [7]. The ion energies were selected to cover the optical penetration depth of visible light used in the Raman-scattering measurements. The implanted samples were annealed at different temperatures between 50°C and 655°C for 30 min in an atmosphere of flowing N_2 gas to determine the thermal stability of multi-vacancies. The samples were then hydrogenated in a remote downstream of hydrogen plasma at 180°C for 30 min. The hydrogenation temperature corresponds to a very effective formation of $\text{H}_2(\text{MV})$ with no Raman line of $\text{H}_2(\text{p})$. Details of the method and hydrogenation conditions have been reported elsewhere [13]. Raman-scattering measurements were performed at room temperature using a 514.5 nm light as an excitation source. In the present study, all the Raman intensities were normalized by the intensity of the optical phonon of silicon measured for the same sample.

Fig. 1 shows the Raman spectra of ion-implanted silicon after thermal annealing at different temperatures followed by hydrogenation at 180°C . Only the Raman line of $\text{H}_2(\text{MV})$ around 3820cm^{-1} was observed among the three hydrogen molecules for the samples hydrogenated without preceding thermal annealing (bottom in Fig. 1(a)). The Raman intensity of $\text{H}_2(\text{MV})$ was

decreased monotonically, with increasing annealing temperature before hydrogenation, and the Raman lines of $\text{H}_2(\text{p})$ around 4160cm^{-1} were increased. It is noted that $\text{H}_2(\text{MV})$ was still observed after annealing at temperatures higher than 550°C . The line shape of $\text{H}_2(\text{MV})$ was hardly affected by annealing temperature. The Raman line of $\text{H}_2(\text{T})$ was not observed for any sample studied here. This may indicate that in silicon with high density of defects, there are other hidden $\text{H}_2(\text{T})$ which cannot be observed by Raman measurement.

The Raman spectra in the Si–H vibration region, shown in Fig. 1(b), consists of many peaks corresponding to Si–H bonds, since there are many kinds of H-terminated multi-vacancies in the ion-implanted sample. Most of the Si–H peaks were annealed below 400°C . After annealing at 550°C , no Raman lines were observed except for a small broad band at 2030cm^{-1} and a prominent peak around 2130cm^{-1} . The latter is the Si–H bonds of H-terminated platelets. The small peak at 2030cm^{-1} is not observed in crystalline silicon without ion-implantation. It may be attributed to the Si–H bond that terminates the multi-vacancy trap of $\text{H}_2(\text{MV})$.

Fig. 2 summarizes the Raman intensity of $\text{H}_2(\text{MV})$ as a function of annealing temperature. The Raman intensity decreased gradually with increasing annealing temperature. No clear annealing stages were observed. This result suggests that several multi-vacancies with different annealing stages are involved in the trap of $\text{H}_2(\text{MV})$.

A theoretical simulation showed that hydrogen molecule is not stable in a H-terminated di-vacancy (V_2H_6) but at the nearest T site to V_2H_6 [9]. The

Fig. 1. Raman spectra of $\text{H}_2(\text{MV})$, $\text{H}_2(\text{p})$ (a), and Si–H stretching (b) for ion-implanted silicon annealed at different temperatures for 30 min followed by hydrogenation at 180°C . The samples were not sequentially annealed. Anneal performed at 240°C , 335°C , 435°C , 550°C and 665°C for each ion-implanted sample.

Fig. 2. The Raman intensity of H₂(MV) as a function of the annealing temperature.

vibrational frequency was calculated to be 3834 cm^{-1} for hydrogen molecule near V₂H₆. The vibrational frequency of hydrogen molecule trapped in tri-vacancy (V₃) and larger multi-vacancies was around 4000 cm^{-1} , comparable to that of H₂(p) and gaseous H₂. Thus, we propose that V₂H₆ is the main trap of H₂(MV). On the other hand, H₂(MV) was observed after annealing up to 600°C. This temperature is much higher than the experimentally determined annealing stage of negative di-vacancy (V₂⁻), 350°C and four-vacancy (V₄⁻), 400°C. Theoretical calculations predicted that multi-vacancies in silicon have magic numbers for their stabilities, i.e. six-vacancy (V₆) [9,14] and ten-vacancy (V₁₀) [9] are much more energetically favorable. However, the frequency of hydrogen molecule in such larger multi-vacancies should become higher. Taking into account that the observed vibrational frequency of H₂(MV) is almost independent of annealing temperature, we tentatively explain the H₂(MV) observed after high-temperature annealing as a result of transformation from V₆ and V₁₀ into V₂H₆ during hydrogenation. The transformation is plausible, since atomic hydrogen in silicon is very aggressive in breaking Si–Si bonds and forming H-related defects. Another possible explanation is that H₂(MV) is trapped in the nearest T site to multi-vacancies of various sizes, e.g. V₂, V₄, V₆ and V₁₀, assuming that the vibrational frequency is not significantly affected by the multi-vacancy size.

In conclusion, we have investigated the thermal stability of multi-vacancy to determine the structure which traps H₂(MV). The results indicated that the main

multi-vacancy trap is H-terminated di-vacancy (V₂H₆), and that it is formed not only by ion-implantation, but also by transformation from larger multivacancies such as V₆ and V₁₀ during hydrogenation. Another possibility is that multi-vacancies of various sizes trap hydrogen molecule at the nearest T site. The Raman line at 2030 cm^{-1} is attributed to the Si–H-terminating multi-vacancy trap of H₂(MV).

Defect-related photoinduced absorption in amorphous silicon

E. Morgado*

Centro de Física Molecular, Instituto Superior Técnico, Technical University of Lisbon, Av. Rovisco Pais, 1049-001 Lisboa, Portugal

Abstract

Photoinduced optical absorption in thin films of hydrogenated amorphous silicon (a-Si:H) is studied over the energy range related to electronic transitions involving the silicon dangling-bond defects, by using the dual-beam Constant Photocurrent Method (CPM). The subgap absorption in the range 0.8–1.4 eV is observed to increase with bias light intensity. Since CPM measures only transitions contributing to the photocurrent, the subgap absorption spectrum in undoped a-Si:H is dominated by transitions between singly occupied D^0 or doubly occupied D^- defect states and conduction band extended states. The photoinduced changes in the subgap absorption are consistent with numerical calculations with a recombination model for a-Si:H which yield dangling bond electronic occupations as a function of photogeneration rate. The results suggest that the observed changes in the optical absorption spectra are mainly determined by changes in the occupation of defects induced by the bias-light. © 2001 Elsevier Science B.V. Keywords: Amorphous silicon; Photoinduced effects; Photoconductivity; Recombination

1. Introduction

Electronic transport and recombination properties of hydrogenated amorphous silicon (a-Si:H) are strongly dependent on localised defect states in the semiconductor mobility gap. The Constant Photocurrent Method (CPM) [1] has been widely used to obtain information on the sub bandgap structure of a-Si:H alloys. Assuming uniform illumination through the thickness d of the sample ($\alpha d \ll 1$) the secondary photocurrent, I_{ph} , measured with coplanar electrodes, is proportional to the optical absorption coefficient and given by $I_{ph} \approx Ae\Phi\alpha d\eta[(\mu\tau)_e + (\mu\tau)_h]$, where A accounts for multiple reflections at film surfaces, e is the electron charge, Φ is the photon flux, α is the optical absorption coefficient, η is the quantum efficiency and $(\mu\tau)_e$, $(\mu\tau)_h$, are the mobility-lifetime products of electrons and holes,

respectively. In the CPM the secondary photocurrent, I_{ph} , is kept constant over the whole spectral range by adjusting the photon flux, $\Phi(h\nu)$, thus ensuring that the occupation of the electronic states and, therefore, the $\mu\tau$ products remain constant. The optical absorption spectrum, $\alpha(h\nu)$, can then be obtained from the measurement of the photon flux, $\alpha(h\nu) \approx \text{constant}/\Phi(h\nu)$. CPM measures only transitions contributing to the photocurrent, i.e., leading to the excitation of carriers to the extended states, and is dominated by the carrier with the higher mobility-lifetime product. It detects only transport paths with low defect densities, being practically insensitive to surface states in micrometer thick a-Si:H samples. By illuminating the sample with a second light beam the occupation of the gap states can be changed and additional information can be extracted from the corresponding absorption profiles. Those measurements with the so called light-bias CPM, or dual-beam CPM, generally yield an increase in the subgap absorption with bias light. The effect has received different interpretations like quasi-fermi level splitting [2–4],

E-mail address: emorgado@alfa.ist.utl.pt (E. Morgado).

defect relaxation [5], change in the electron recombination lifetime [6,7], and has been observed in undoped [2–4,6] as well as in n-type doped [7] a-Si:H thin films.

Quantitative analysis have been made by fitting the photoconductivity data with numerical models based on Simmons–Taylor statistics and a distribution of gap states consisting of band tails and different pictures for the defects, including two Gaussian bands of midgap donor-like and acceptor-like states [3,4], three Gaussian bands of midgap positively charged defect states above and negatively charged states below midgap as well as paramagnetic states close to midgap [8], a model later expanded with two more Gaussian defect distributions close to the valence and conduction bands [9].

In the present work we report dual-beam CPM measurements on undoped a-Si:H and discuss the results on the basis of a numerical recombination model involving band-tail states and correlated dangling bonds in their three states of charge D^+ , D^0 , D^- .

2. Experimental details

The sample used in this study is an undoped a-Si:H thin film produced by Plasma Enhanced Chemical Vapor Deposition from silane gas. The dual-beam CPM setup uses a tungsten-halogen lamp and a monochromator to produce the monochromatic probe beam. The AC photocurrent signal is detected by the lockin-technique with a chopper frequency of 10 Hz. Control of the probe beam light flux, in order to ensure a constant photocurrent, is obtained by varying the voltage applied to the lamp in combination with a set of neutral density filters. The probe beam light intensity is measured by a pyroelectric detector with a beam-splitter. The light bias beam is from a 2 mW He–Ne laser (633 nm) with appropriate attenuation. In order to minimise photodegradation effects during the CPM measurements, the sample was previously exposed to the laser beam over 2 h. All measurements were performed at room temperature.

3. Results and discussion

3.1. Light-bias CPM data

In Fig. 1 it is shown the CPM deduced optical absorption spectra for different values of the intensity of the laser bias beam in terms of the corresponding photogeneration rate in the sample. The CPM measurements have been made for a constant value of the photocurrent in the sample which corresponds to an

Fig. 1. CPM-derived optical absorption spectra of the a-Si:H sample for several bias beam intensities.

estimated photogeneration rate of $10^{14} \text{ cm}^{-3} \text{ s}^{-1}$ much lower than those produced by the bias beam in the experiments. This means that the electronic states occupation imposed by the laser beam is practically unperturbed by the photoconductivity measurements. The CPM-derived spectra were calibrated by matching to the optical absorption coefficient obtained from Optical Transmission Spectroscopy for the gap energy of a-Si:H around 1.7 eV. In the absorption in Fig. 1 one can distinguish the exponential absorption region related to transitions between band tail states for $1.5 \text{ eV} < E < 1.7 \text{ eV}$, and the sub gap region for $E < 1.5 \text{ eV}$ which is related to transitions involving the deep midgap states. Interference fringes due to multiple reflections at film surfaces are apparent in the low absorption region. A clear increase in the subgap absorption with bias light intensity can be observed in the spectra of Fig. 1. The dependence of the optical absorption coefficient on the bias photogeneration rate for several photon energy values is shown in Fig. 2. These results are in qualitative agreement with reported trends [2–9]. In the exponential absorption region, the spectra show a common Urbach slope of 50 meV. The deep defect density is currently estimated by the CPM technique, either from the integrated excess absorption up to the Urbach tail, or from the absorption coefficient at a single energy. Taking into account the different proposed calibration factors for the absorption coefficient at 1.2 eV [10] an estimate of the defect density is obtained in the range $3\text{--}7 \times 10^{16} \text{ cm}^{-3}$.

Fig. 2. Subgap absorption coefficient as a function of bias beam intensity for several energies.

Fig. 3. Simulated dependence of dangling bond charge state densities on the bias beam intensity.

3.2. Numerical recombination model

In the following we compare the dual-beam CPM data with results from a numerical recombination model for a-Si:H which yields dangling bond occupations as a function of photogeneration rate [11]. The silicon dangling bond defect is represented by correlated discrete levels for the states of charge D^+ , D^0 , D^- , with respective occupation functions f^+ , f^0 , f^- and total density N_D . Conduction and valence band-tails of localised states have exponential distributions with characteristic energies E_{oc} and E_{ov} , respectively, and have electronic occupations determined by Simmons and Taylor statistics. In the dual-beam CPM the strong bias beam determines the electronic occupation of the gap states which is then sensed by the low intensity probe beam. In Fig. 3 one can see the calculated dependences of the densities of the different dangling

bond charge states on the photogeneration rate from the bias beam. The parameter values are: $N_D = 3 \times 10^{16} \text{ cm}^{-3}$, $E_{oc} = 30 \text{ meV}$, $E_{ov} = 50 \text{ meV}$, $E_c - E_{D^0} = 1 \text{ eV}$, $E_c - E_D = 0.6 \text{ eV}$, where E_c refers to the conduction band mobility edge, and capture cross sections of 10^{-17} cm^2 . In undoped a-Si:H the photocurrent is dominated by electrons; therefore, the CPM deduced optical absorption spectra in the low energy range reflect transitions between electron occupied gap states, the D^0 and D^- states, and the conduction band of extended states. According to Fig. 3, the quantity $N_D f^0 + N_D f^-$ increases with the photogeneration rate, consistently with the sub gap optical absorption enhancement observed in Figs. 1 and 2. A more detailed analysis that might separate the individual contributions of the D^0 and D^- states in the experimental data would require elaborate filtering procedures and extension to lower spectral energy ranges.

4. Conclusions

Photoinduced changes in the subgap optical absorption spectra of a-Si:H derived from the dual-beam CPM technique are reported. The effect is investigated over three orders of magnitude in the bias beam intensity. The observed optical absorption enhancement is qualitatively consistent with results from a recombination model, suggesting that the effect is associated with the increase in the combined density of singly and doubly occupied dangling bond defect states for increasing bias light intensity.

Hydrogen-induced formation of defects nanoclusters in crystalline silicon

Kh.A. Abdullin*, Yu.V. Gorelinskii, B.N. Mukashev

Institute of Physics and Technology, 480082 Almaty, Kazakhstan

Abstract

Low-temperature hydrogen-assisted clusterization of aluminum impurity in silicon has been studied. It was found that hydrogen can decrease the diffusion barrier of the Al atom and initiate the migration of Al atoms at 180–200 K. As a result, an interstitial aluminum pair formation takes place in H-implanted silicon. The implantation with a dose $\geq 1 \times 10^{16}/\text{cm}^2$ causes formation of the clusters containing more than two aluminum atoms. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Enhanced diffusion; Nanoclusters

1. Introduction

Interstitial aluminum atom appears as a result of high-energy particle (e^- , p^+ , α^{++}) irradiation and the interaction of mobile self-interstitials Si_i and substitutional Al_s through the replacement mechanism [1,2]: $\text{Si}_i + \text{Al}_s \rightarrow \text{Si}_s + \text{Al}_i$. The Al_i is placed in the T_d interstitial site and the EPR spectrum Si-G18 [1–3] corresponds to a $(2+)$ charge state of the defect. A DLTS level $E_v + 0.18 \text{ eV}$ has been identified as arising from the second donor state $(+/2+)$ [4,5]. The Al_i is stable up to 20°C, when it begins to migrate with an activation energy of 1.2 eV and is replaced by G19–G21 defects. The G19 and G20 defects were identified as $\text{Al}_i\text{--Al}_i$ pairs, the G21 as unknown defect associated with one aluminum atom. The activation energy of the Al_i atom diffusion is reduced from 1.2 to 0.3 eV under injection condition [5] and the Al_i defect is annealed at room temperature under an injection current of 1 A/cm^2 in a time of $\sim 10^3 \text{ s}$.

In this paper, we discuss the phenomenon of hydrogen-enhanced diffusion of aluminum atom in silicon at $T \sim 180\text{--}200 \text{ K}$ [6,7]. Low-temperature hydrogen-enhanced diffusion of Al atoms is a unique

phenomenon, which may be caused by a tunnel mechanism.

2. Experimental procedure

Samples were fabricated from floating-zone-grown silicon (FZ-Si), doped with 5×10^{16} aluminum/ cm^3 . Hydrogen was incorporated either by proton implantation at 880 K or by thermal annealing in the presence of hydrogen species. In the latter case, the samples and hydrogen-free control ones were irradiated at 80 K with 30 MeV protons. Since the proton range ($\sim 4 \text{ mm}$) is far beyond the thickness of sample ($\sim 0.5 \text{ mm}$), hydrogen implantation in the bulk of the sample was completely avoided in this case.

3. Experimental results

EPR spectra Si-AA15 and Si-AA16 grow upon thermal annealing at $\sim 180\text{--}200 \text{ K}$ in the hydrogen-implanted samples as well as in the samples which were heat-treated in the presence of water vapor, and are not observed in control samples [6–8]. The Si-AA15 spectrum is the most dominating in comparison with the other spectra and consists of 11 groups of lines at any

*Corresponding author. Tel.: +7-3272-546-812; fax: +7-3272-545-244.

E-mail address: abdullin@sci.kz (K.A. Abdullin).

orientation of magnetic field in the $(0\bar{1}1)$ plane. A splitting between the lines does not pass through zero, therefore, the cause of the splitting is hyperfine interaction. The EPR spectrum consisting of 11 groups of lines (Fig. 1) can be formed only due to two nuclei (α and β) with a 100% abundant isotope of $I = 5/2$ involved in the structure of the center. These nuclei in our samples can be only nuclei of aluminum atoms involved in the defect. The Si-AA15 spectrum was stable up to room temperature and disappeared at 300 K for 10 min. The second spectrum, Si-AA16 ($S = 1/2$), has nearly isotropic g -tensor and consists of six groups of lines. Therefore, one nucleus with a 100% abundant isotope of $I = 5/2$ (^{27}Al) is involved in the structure of the AA16 defect. Its ^{27}Al hyperfine interaction is also nearly isotropic with weak trigonal distortion: $A_{||} = 823$ MHz, $A_{\perp} = 836$ MHz. The width of individual lines of the AA16 spectrum depends slightly on the direction of the magnetic field. The Si-AA16 spectrum is stable in the narrow temperature interval from 180 to 200 K. The known isolated aluminum interstitial Al_i (EPR spectrum G18 [1,2]) is not observed in both implanted and control samples immediately after 80 K implantation of hydrogen but appears in all samples annealed at ~ 260 – 280 K and there is no clear correlation of the AA15 and G18 spectra behavior.

Hyperfine interaction may be analyzed in terms of a one-electron wave function for the unpaired electron [9]. The observed hyperfine structure of the AA15 defect indicates that $\sim 18\%$ ($\sim 10\%$) of the unpaired spin wave function is located on the $\alpha(\beta)$ Al atoms and has $\sim 45\%$ 3s and $\sim 55\%$ 3p character. The resolved ^{29}Si hyperfine

structure can also be seen, its intensity corresponds to ~ 4 – 6 neighboring sites accounting for only $\sim 5\%$ of the wave function. The same analysis for the AA16 center indicates that about 30% of the wave function is localized on the single aluminum atom, with mostly 3s-like character ($\sim 80\%$).

The concentration of the Al–Al pairs (AA15 defects) varies proportionally with the hydrogen content and is increased in the range of the implantation doses from 1×10^{15} to $\sim 5 \times 10^{15}$ H/cm 2 . But the implantation with a dose of $\sim 1 \times 10^{16}$ H/cm 2 (this dose corresponds to the hydrogen concentration of $\sim 2 \times 10^{18}$ H/cm 3) results in the low AA15 defect concentration or does not introduce the AA15 pairs at all. A new complex EPR spectrum emerges instead (Fig. 2). The spectrum is observed only when the magnetic field direction coincides with the $\langle 100 \rangle$ axis of the sample. The complex spectrum disappeared upon annealing at room temperature, but a second new spectrum, very similar to the first one, emerged at 100°C annealing (Fig. 2). Permanent changes of the EPR spectra are observed up to 160 – 185°C annealing, then the complex spectrum and the Si-G18 spectrum are substituted by a spectrum similar with the Si-G19 spectrum (Al_i – Al_s pair). We suppose that the observed complicated spectrum belong to Al-containing defects, which are formed as a result of prolonged hydrogen-enhanced diffusion and precipitation of Al atoms. Thus, the defects consist of more than two Al atoms and are Al-containing nanoclusters.

4. Discussion

Hyperfine structure of the EPR spectrum Si-AA15 establishes, unambiguously, that two aluminum atoms are incorporated into the AA15 defect. The density of

Fig. 1. (a) The EPR spectrum Si-AA15 at 77 K in FZ-Si:Al sample implanted with protons at 80 K to a dose of 3×10^{15} /cm 2 and annealed at ~ 200 K. Calculated positions of lines are also shown. (b) The formation of 11 groups of EPR lines due to hyperfine interaction of two nearly equivalent nuclei with a 100% abundant isotope of $I = 5/2$.

Fig. 2. EPR spectra of a FZ-Si:Al sample in which Si-AA15 and Si-AA16 spectra were observed and which, after room temperature annealing was again implanted by protons at 80 K to a dose of 3×10^{15} /cm 2 and then annealed at 195 K (1) and 100°C (2). One of the six Si-G18 spectrum lines is shown, which corresponds to a transition with $m_I = 1/2$.

defect AA15 is rather high and it is a dominant one after annealing at 200 K. In accordance with our estimation, the majority of aluminum atoms participate in the formation of the pairs. To reach other Al atoms and to form the Al–Al pairs, Al atoms should migrate at least by a distance of ~ 100 lattice constants. The Al atoms have to migrate as defect complexes. The unusual feature of such a migration is that low temperature is required (180–200 K).

The observed migration of Al atom cannot be an injection-assisted one. Indeed, if we propose that the annealing rate of Al_i under the conditions of irradiation is the same as in the case of the injection [5], the typical time of annealing will be about 10^9 h at the temperature of implantation (80 K), that allows us to eliminate the injection as a cause of enhanced migration of the Al atoms. Our results demonstrate that the presence of hydrogen atoms and radiation defects at low (180–200 K) temperature is necessary (and may be sufficient) to create the AA15 pairs. Hydrogen-enhanced migration of Al atom takes place due to the formation of some (Al–H) defect capable to migrate at 200 K. But $\text{Al}_i + \text{H}$ and $\text{Al}_i + \text{V}$ (Si–G9 [10]) defects are stable up to 400 K, so the (Al–H) mobile defects have to have an interstitial character. The estimation of the activation energy for diffusion of (Al–H)_i center gives the value as 0.22 eV.

The AA16 center is a suitable candidate for the (Al_i+H) defect. Indeed, the defect has a very narrow range of thermal stability (180–200 K) that coincides with the temperature of AA15 spectrum appearance. About 30% of the wave function appears to be accounted for on the Al atom. It is comparable to the case of the Al_i tetrahedral interstitial ($\sim 38\%$) [3]. The atomic orbitals are of 20% p character. This fact implies that the Al atom incorporated in the structure of the AA16 defect is slightly displaced from T_d site by some disturbance. It can be speculated that two atoms—an Al_i^{2+} and an $\text{H}_{T_d}^-$ —situated close to the two nearest tetrahedral interstitials, T_d , form the AA16 defect (Fig. 3). The atoms Al and H have to be displaced towards each other due to Coulomb attraction that can result in a decrease of the energy barrier between these two atoms. The migration barrier of (Al_i–H) defect would thus be expected to be reduced essentially. The low temperature of Al atom migration may be a consequence of a tunnel mechanism for the (Al_i–H) defect diffusion. Certainly, theoretical calculations have to be conducted in order to explain low-temperature hydrogen-enhanced migration of Al atom in silicon.

Fig. 3. Model of a $(\text{Al}_i^{2+} - \text{H}_{T_d}^-)$ center which can be responsible for Si-AA16 spectrum appearance and enhanced diffusion of Al atom.

Note that at low- and room-temperature, a solid solution of the Al impurity in silicon is in supersaturated state, but its decay is prevented by the low value of diffusion coefficient. The enhanced diffusion opens possibilities for the formation of a phase enriched with impurity atoms. The Al–Al pair (the A15 center) can be considered as the nucleus of a new phase, and the association of additional Al atoms with the AA15 defect can occur.

Thus, radiation-induced and hydrogen-enhanced diffusion may lead to formation of micro- and nanoclusters of a new, aluminum-enriched phase in the silicon matrix. It is of interest to check the existence of hydrogen-accelerated migration of the impurity boron and gallium, whose chemical properties are similar to aluminum in many respects.

Abstract

The systematical low-temperature (4.2 K) photoluminescence (PL) study of the formation kinetics of optically active centers in H and He implanted CZ Si, annealed in the temperature range of 200–1000°C is presented. The samples were implanted with H (energy $E = 80$ keV, dose $D = 10^{15}/10^{16}$ cm⁻²) and He ($E = 150$ keV, $D = 5 \times 10^{14}$ cm⁻²) ions. It was found that the annealing of H or He implanted samples leads to the appearance and evolution of a number of zero-phonon lines as well as of broad bands. The origin of the observed lines and bands is discussed. It is assumed that the strong stresses around hydrogen-related structural defects (voids, bubbles) during the annealing at 500–700°C of H implanted Si lead to the formation of a specific optical center M' (~ 1.012 eV PL line). © 2001 Elsevier Science B.V. 1. Introduction

H- and He-implanted Si has been studied extensively because of considerable technological importance of these atoms for the modification of the material properties [1–5]. It was shown that hydrogen in Si can passivate the shallow acceptor and donor impurities [6,7], oxygen-related thermal donors and other deep-level defects [1,8,9], dislocations [1,10], grain boundaries and dangling bonds [1,11]. On the other hand, hydrogen can form complexes with different impurities (C, O, transition-metals, etc.) in Si, which introduce new levels

in the band gap [12,13]. It was also found that the He atoms can be involved in the defect formation process of ion-implanted Si [14]. This work extends previous PL spectroscopy investigations of the H(He) implanted Si at post-implantation annealing, which were done earlier [13–16]. Emphasis is put on complex formation at high-temperature ($> 600^\circ\text{C}$) annealing. Evidence for a number of hydrogen- and helium-induced optical active complexes in ion-implanted Si is presented. The possible structure of these complexes is discussed.

2. Experimental

The material employed in these PL measurements was (100)-oriented Czochralski (CZ) silicon doped with

E-mail address: alexander.ulyashin@fernuni-hagen.de (A.G. Ulyashin).

either phosphorus (n-type, 10 Ω cm) or boron (p-type, 12 Ω cm). The concentration of oxygen in all samples was specified as of about $\sim 8 \times 10^{18} \text{ cm}^{-3}$, and the carbon concentration was between 10^{16} and 10^{17} cm^{-3} . The samples were implanted with H ($E = 80 \text{ keV}$, $D = 10^{15}/10^{16} \text{ cm}^{-2}$) and He ($E = 150 \text{ keV}$, $D = 5 \times 10^{14} \text{ cm}^{-2}$) ions. An isochronal annealing of 20 min was carried out between 200°C and 1000°C in vacuum. PL measurements were performed at 4.2 K with the samples immersed in liquid helium. PL was excited by the Ar 488 nm laser line. The incident laser intensity was typically between 10 and 60 mW. The emission light was dispersed using a 0.6 m single grating monochromator and detected with a liquid-nitrogen-cooled Ge diode. Conventional lock-in detection was employed with the chopper ($\sim 20 \text{ Hz}$) placed in the exciting laser beam.

3. Results and discussion

Fig. 1 shows typical PL spectra of p-type CZ Si after 80 keV H⁺ implantation with dose 10^{16} cm^{-2} and following annealing at various temperatures. The spectra exhibit several intense luminescence lines labeled as $B_{\text{NP}}^{\text{BE}}$, $B_{\text{TA}}^{\text{BE}}$, $B_{\text{TO}}^{\text{BE}}$, and $B_{\text{TO+O}}^{\text{BE}}$ in the near-band-gap region. These lines arise from bound exciton (BE) recombination at boron as a shallow doping impurity. The luminescence in this spectral range includes the no-phonon (NP) line (optical transitions without the creation of phonons) and TA, TO, TO + O lines (optical transitions with the participation of momentum-conserving phonons, where TA, TO and O denote the transverse acoustical, transverse optical and zone center phonon, respectively). The assignments of these PL lines have been well established earlier [17]. The dominating PL line is the TO-phonon replica of the bound excitons $B_{\text{TO}}^{\text{BE}}$ at 1.093 eV. Besides these lines, three broad bands with energies of 1.029 (H1), 0.972 (H2) and 0.933 (H3) eV were observed in as-implanted and at 200°C annealed samples. The H1 and H2 peaks can be interpreted as the NP line and TO-phonon replica, respectively, which originate from the radiative recombination at hydrogen-related defects. The H3 band can be attributed to another but also hydrogen-related defect. Such identification of the H1–H3 bands with hydrogen-related defects is based on the fact that these bands are absent in the spectra of Si after helium implantation with following annealing (see below). It is necessary to note that the H1–H3 bands were detected in the PL spectra of Si after hydrogenation [7]. Jonson et al. [7] suggested that hydrogen-containing extended defects ($\langle 111 \rangle$ platelets) are responsible for the H1–H3 bands. One can see (Fig. 1) that annealing at 200°C results in a significant increase (up to ~ 10 times) of the intensity of the 1.0186 eV (W-line) PL NP line. The annealing at 300°C and 400°C produces a broad band and (at 400°C)

Fig. 1. PL 4.2 K spectra of H implanted ($E = 80 \text{ keV}$, $D = 10^{16} \text{ cm}^{-2}$) 12 Ω cm p-type Cz Si annealed in vacuum at different temperatures for 20 min.

an additional low-intensity NP line at 1.0399 eV (X-line). The luminescence centers responsible for the W- and X-lines are observed usually in Si after irradiation with high-energy particles such as neutrons and different kind of ions [18,19]. The microscopic structure of the W defects is identified as a trigonal center which involves Si interstitial or/and hydrogen atoms [14,20,21]. The X center possibly can be attributed to a vacancy-type defect [19–22]. Annealing of H-implanted Si layers at and above 500°C causes a rapid growth of the intensity of D1–D4 bands. These bands might be related to dislocations [23]. At this stage of the thermal treatment, new NP PL lines at 1.012 eV (M') and its TO-phonon

replica at 0.954 eV (M'_{TO}) also occur in the PL spectra. Annealing at higher temperatures (600–1000°C) of 80 keV H^+ implanted with dose of 10^{16} cm^{-2} p-type CZ Si leads to the appearance of dislocation-related PL bands D1–D4 and to the D' band which is somewhat wider than D1 and has a peak at about 0.78 eV (Fig. 1). Fig. 2 shows the PL spectrum for n-type H implanted Si (with dose of 10^{15} cm^{-2}) after the 700°C annealing. One can see that in this case, the only M' (M'_{TO}) and D' bands are present but not D1–D4 ones. Moreover, the spectral shape of M' (M'_{TO}) and D' bands can be observed better in this case. It was also found that for n-type Si, the main peculiarities of PL spectra after the annealing at temperature range 200–1000°C are similar to those for p-type Si shown in Fig. 1. An analysis of the spectra for different Si samples allows us to assign the D' band to the recombination on defects which are different from those responsible for the D1 band. Fig. 3 shows the dependence of M' and D' intensities versus annealing temperature for n-type H implanted Si. It is necessary to note that the D' band was detected earlier in the PL spectra of Si implanted by H^+ and He^+ after annealing at 1000°C [16]. This band was recently also observed in PL spectra of Si samples implanted with H^+ and O^+ ions after the high-pressure–high-temperature annealing [24], in multicrystalline Si [25] and in Si–Ge structures with Ge quantum dots [26]. All these facts show that D' band appears in strained Si structures. This allows us to assume that the gettering and precipitation (near dislocations) of residual impurities such as carbon, oxygen or Si self-interstitials during high-temperature annealing might be responsible for the appearance of this band. Some assumptions about the nature of the M' and M'_{TO} bands also can be made. It is necessary to note that in Ref. [23], the PL spectra stacking-faults-related band D6 at 4.2 K ($\sim 1.0126 \text{ eV}$, similar to the energy of the M' line) was detected in plastically deformed silicon samples. It was observed that the D6 line disappeared after heat treatments at 390°C. In our case, the structure

Fig. 2. PL 4.2 K spectrum of H implanted ($E = 80 \text{ keV}$, $D = 10^{15} \text{ cm}^{-2}$) $10 \Omega \text{ cm}$ n-type Cz Si annealed in vacuum at 700°C for 20 min.

Fig. 3. PL (4.2 K) intensity dependencies of the D' and M' bands versus annealing (20 min) temperatures.

of the defects which are responsible for the M' band is different from stacking-faults because of the different temperature stability of the M' luminescence centers (Fig. 3). It can be assumed that during the annealing of H-implanted Si samples at 500–700°C, the formation of hydrogen-related nanovoids or nanobubbles occurs. We suggest that this process is responsible for the appearance and growth of M' (M'_{TO}) bands. Internal stresses can lead to the formation of the optically active structural defects. Similar to the M' band, the WL (NP) and WL(TO) bands were detected also in Si–Si/Ge and Si–Ge structures with Ge quantum dots [26,27], which are heavily stressed structures. Such stressed structures can be formed in H implanted Si due to hydrogen and oxygen gettering and precipitation at the buried implantation damage layers at high-temperature annealing [28]. Fig. 4 shows the PL spectra of He implanted (150 keV , $5 \times 10^{14} \text{ cm}^{-2}$ dose) n-type CZ Si annealed isochronal at different temperatures. The well-known NP lines with energies 0.9697 eV (A), 0.7894 eV (C), 0.9500 eV (G), 0.9353 eV (T), 0.9652 eV (I) and 0.7610 eV (Q) as well as D1–D4 bands can be observed in these spectra. The A, C, G, T, I and Q lines are related to the point defects, which include in their structures the residual impurities such as carbon, oxygen and hydrogen [12,14,18,19]. Annealing of the He-implanted samples at 200°C and 300°C produces also a high intensive line Z2 (1.012 eV) which is connected with the He-containing PL centers [14,19,20].

4. Conclusions

Our experimental results of 4.2 K PL measurements of the H and He implanted and annealed CZ Si can be summarized as follows:

1. Broad bands with energies of 1.029 (H1), 0.972 (H2) and 0.933 (H3) eV were observed in as hydrogen implanted and in annealed at 200°C after the

Fig. 4. PL 4.2 K spectra of He implanted ($E = 150$ keV, $D = 5 \times 10^{14} \text{ cm}^{-2}$) $10\Omega\text{cm}$ n-type Cz Si annealed in vacuum at different temperatures for 20 min.

implantation samples. The H1 and H2 peaks can be interpreted as the NP line and TO-phonon replica, respectively, which originate from the radiative recombination at hydrogen-related defects.

2. Annealing of the H implanted samples at 500–700 °C results in the appearance of the PL line at 1.012 eV (M') and its TO-phonon replica at 0.954 eV (M'_{TO}). These lines can be attributed to the specific defects induced by the internal stresses around hydrogen-related defects (nanovoids or nanobubbles).
3. Annealing of the H implanted samples at 600–1000 °C results in the appearance of D' band with the energy of 0.78 eV. This band can be attributed to the residual impurities near the dislocation region.
4. Annealing of the H or He implanted samples at 500–1000 °C results in the appearance of the D1–D4 bands, which can be attributed to the radiative recombination at dislocation-related centers.

Hydrogen enhanced thermal donor formation in p-type Czochralski silicon: application to low temperature active defect-engineering

A.G. Ulyashin*, R. Job, I.A. Khorunzhii, W.R. Fahrner

Department of Electrical Engineering, University of Hagen, Haldener Street 182, D-58084 Hagen, Germany

Abstract

The incorporation of hydrogen into the p-type Czochralski (Cz) silicon by a plasma results in an enhanced thermal donor (TD) formation at temperatures around 400°C. Counter doping by the TDs and a rapid p–n junction formation occur in the p-type Cz Si. It is shown that the controlled TDs formation can be used for the low-temperature production of device structures: p–n junctions, p–n–p structures and structures with gradient doping. The characterization of the samples was done by the depth resolved spreading resistance probe (SRP) analysis. A kinetic model for the analysis of the hydrogen-enhanced TDs formation in the as-grown as well as in the Cz Si samples with denuded zone is developed. It can be concluded, that the controlled hydrogen enhanced TDs formation can be used as an alternative low-cost, low-temperature doping method, which might be favorable for active defect-engineering in the Cz Si. © 2001 Elsevier Science B.V. 1. Introduction

The incorporation of hydrogen into the Czochralski (Cz) silicon by a plasma results in an enhanced thermal donor (TD) formation [1–5]. As a consequence, the n-type doping of the Cz Si can be provided at low (350–450°C) temperatures. Recently, it was shown [6–15] that the n-type counter doping of the initial p-type Cz Si material can be observed. TD concentrations up to $2\text{--}3 \times 10^{16} \text{ cm}^{-3}$ can occur, depending on the process temperatures, plasma power and treatment times and on the concentration of the interstitial oxygen in the Cz Si substrate. Therefore, a counter doping by the TDs and a rapid p–n junction formation can be observed in the p-type Cz Si if the acceptor concentration is not higher than about 10^{16} cm^{-3} . Moreover, it was shown that

when the interstitial oxygen concentration was changed by the three-step high temperature oxygen out-diffusion [11], which leads to the formation of the so-called denuded zone (DZ), a transistor type device structure (p–n–p) due to the hydrogen enhanced TDs formation was formed. The goal of the present paper is (i) the experimental investigations of the carrier profiles modified by the hydrogen enhanced TDs formation in the Cz Si samples with different thermal prehistory and (ii) the development of a kinetic model for the analysis of the hydrogen enhanced TDs formation in the as-grown as well as in the Cz Si with the DZ.

2. Experimental

The investigations were done on standard p-type (100) $10 \Omega \text{ cm}$ Cz Si wafers with thickness of about 370–380 μm . The carbon concentration was specified by $[C] \leq 5 \times 10^{16} \text{ cm}^{-3}$. The oxygen concentration was

*Corresponding author. Fax: +49-2331-987-321.

E-mail address: alexander.ulyashin@fernuni-hagen.de (A.G. Ulyashin).

$\approx 7\text{--}8 \times 10^{17} \text{ cm}^{-3}$ (specified). The one-step process, which involves the out diffusion of oxygen at high temperature (1100°C for 5 h in flowing nitrogen) was applied for the generation of the DZ. For the two-step hydrogen enhanced TDs formation process, the as-grown samples and samples with the DZ were exposed by a RF hydrogen plasma for 1 h at $T \approx 260^\circ\text{C}$ (first step) in a standard PECVD setup at 110 MHz, applying a hydrogen flux of 200 sccm (standard cubic centimeters per minute) and a power of 50 W. For comparison, another version of the first step process for the as-grown samples was done using a DC plasma reactor, where a plate voltage of 500 V and a current density of $400 \mu\text{A cm}^{-2}$ was applied for 10 min at 400°C . As the second step of the hydrogen enhanced TDs formation process, the post-hydrogenation annealing was done at 400°C and 450°C in air. After annealing, the samples were rapidly cooled down to room temperature. The samples were analyzed by the SRP measurements. The SRP measurements were done on a 4-point probe instrument with tungsten carbide tips. For the SRP measurements, the samples were beveled on a rotating quartz plate.

3. SRP analysis of hydrogen enhanced TDs formation in p-type Cz Si

Fig. 1 exhibits the resistance profiles of a $10 \Omega\text{cm}$ p-type Cz Si treated for 10 min by a DC plasma at 400°C and then annealed at 400°C and 450°C in air. One can see that at the initial stages of the hydrogen enhanced TDs formation (annealing time < 5 min), a strong compensation of the acceptors occurs which leads to the gradient carrier profiles in the sub-surface region of the Cz Si sample. After about 8 min annealing, the SRP profiles exhibit p–n junctions moving rapidly into the sample bulk with longer annealing times. For the case of the post-hydrogenation annealing at 450°C , the moving of the p–n junctions into the bulk is faster than at 400°C annealing. Almost the same behavior was observed in the case of the hydrogenation at 250°C for 1 h by a HF plasma with subsequent annealing at 400°C (Fig. 2). One can conclude that during the hydrogenation (first process step), the saturation of the sub-surface layer by hydrogen occurs without any essential (250°C hydrogenation) or slight (400°C hydrogenation) modification of the carrier profiles. At this stage, hydrogen can be involved in the structure of different complexes (molecular species) [16,17]. The total hydrogen concentration in the sub-surface layer is $\sim 10^{19} \text{ cm}^{-3}$ [18]. During the second stage (400°C , 450°C annealing), a release of the atomic hydrogen from these species occurs which provides the hydrogen enhanced TDs formation in the Cz Si. This formation leads to the gradient doping, due to the compensation, or to the p–n junction appearance

Fig. 1. The SRP profiles for the as-grown p-type Cz Si treated for 10 min by a DC hydrogen plasma at 400°C with subsequent annealing at 400°C and 450°C . The peaks of the resistance curves correspond to the p–n junction location.

Fig. 2. The SRP profiles for the as-grown p-type Cz Si treated for 1 h by a HF hydrogen plasma at 250°C with subsequent annealing at 400°C . The peaks of the resistance curves correspond to the p–n junction location.

due to the counter doping in the initial p-type Cz Si. The p–n junctions exhibit the characteristics of linear graded junctions [7,9,12,13]. The diodes prepared by the hydrogen enhanced TDs counter doping of the p-type Cz Si were analyzed in [12,13]. It can be concluded that for a given Cz Si material (the oxygen concentration was the same in all cases), the rate of the hydrogen enhanced TDs formation depends mainly on the temperature and time of the post-hydrogenation annealing but not on the

method of the hydrogenation. Fig. 3 exhibits the resistance profiles of a 10 Ω cm p-type Cz Si with the DZ treated for 1 h at 250°C by a HF hydrogen plasma and then annealed at 400°C in air. One can see that in this case, the formation of the buried n-type region after 0.5 h of post-hydrogenation annealing occurs. This region originates as a result of the suppressed TDs formation in the DZ [11]. Thus, the formation of a transistor type (p–n–p) structure is possible.

4. Kinetic analysis of hydrogen enhanced TDs formation

We can describe the time dependence of the concentrations of atomic [H] and molecular [H₂] hydrogen as well as the TDs concentration [TD] by [15]

$$\frac{\partial[H]}{\partial t} = D_H \frac{\partial^2[H]}{\partial x^2} - K_1[H]^2 + 2K_2[H_2], \quad (1)$$

$$\frac{\partial[H_2]}{\partial t} = \frac{1}{2}K_1[H]^2 - K_2[H_2], \quad (2)$$

$$\frac{\partial[TD]}{\partial t} = C[O]^3[H] \left(1 - \frac{[TD]}{[TD]_{\max}}\right), \quad (3)$$

where D_H is the diffusion coefficient of the atomic hydrogen in the Si which is given by [19]

$$D_H = D_0 \exp\left(-\frac{E_a}{kT}\right), \quad (4)$$

where E_a is the activation energy of the diffusion ($E_a = 0.48$ eV) and $D_0 = 9.4 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$; K_1 is the coefficient of the H₂ molecules formation, $K_1 = 8\pi R_0 D_H$ (where $R_0 = 5 \text{ \AA}$ [20]); K_2 is the dissociation constant of the H₂-molecules, $K_2 = \nu \exp(-E_b/kT)$, where ν is the vibrational frequency for the dissociation of H₂ molecules ($\nu = 10^{13} \text{ s}^{-1}$ [21]) and E_b is the binding energy of H₂ ($E_b = 1.6$ eV [20]); $[TD]_{\max} = 10^{16} \text{ cm}^{-3}$ is the maximal thermal donors concentration; and C is a free

parameter. In our calculations, we used $C \approx 2.2 \times 10^{-60}$ and $1.1 \times 10^{-60} \text{ cm}^{-3}$ at 450°C and 400°C, respectively, to fit the experimental data.

In case of the DZ formation, the time dependence of the interstitial oxygen concentration [O] at the depth x from the surface for an annealing temperature T_a at a time t is given by the error function [22]

$$[O] = [O]_s + ([O]_0 - [O]_s) \operatorname{erf}\left(\frac{x}{2\sqrt{D_{OX} \tau t}}\right), \quad (5)$$

where [O] is the initial oxygen concentration for the as-grown sample; $[O]_s$ is the solubility of oxygen in the Si at a temperature T ; $D_{OX} \tau$ is the diffusion coefficient of oxygen in silicon at a temperature T_a . $[O]_s$ and $D_{OX} \tau$ are given by [22]

$$D_{OX} \tau = 0.13 \exp\left(-\frac{2.53 \text{ eV}}{kT}\right) \text{ cm}^2 \text{ s}^{-1},$$

$$[O]_s = 9 \times 10^{22} \exp\left(-\frac{1.52 \text{ eV}}{kT}\right).$$

The boundary conditions are the following:

At the front side ($x = 0$):

$$[H] = [H]_0 = 10^{18} \text{ cm}^{-3} \quad \text{when } t < t_H, \quad (6)$$

$$\left.\frac{d[H]}{dx}\right|_{x=0} = 0 \quad \text{when } t > t_H. \quad (7)$$

where t_H is the time of the hydrogenation, $[H]_0$ was taken as $[H]_0 = 10^{18} \text{ cm}^{-3}$ to fit the experimental data $[H]_{\text{total}} = [H] + [H_2] = \sim 10^{19} \text{ cm}^{-3}$ for $t = t_H$.

At the backside ($x = x_{\max}$):

$$\left.\frac{d[H]}{dx}\right|_{x=x_{\max}} = 0. \quad (8)$$

Initial conditions:

$$[H(x)] = 0; \quad [H_2(x)] = 0; \quad [TD(x)] = 0. \quad (9)$$

The system of Eqs. (1)–(3) with boundary conditions (6), (7), (8) and initial conditions (9) has been solved numerically.

Figs. 4 and 5 show the calculated electron concentrations originating from the TDs (double donors) during the annealing of the as-grown Cz Si at 400°C after the hydrogenation at 250°C for 1 h and during the annealing at 400°C and 450°C after the hydrogenation at 400°C for 10 min, respectively. One can see (Figs. 1, 2 and 4) that the calculations give a rather correct description for the p–n junctions' location. In case of the Cz Si with the DZ, calculations (Fig. 6) give also rather correct description for the location of the first p–n junction and a somewhat deeper location than in the experiment (Figs. 3 and 6) for the second p–n junction. This fact shows that not only the out diffusion of oxygen is important for the TDs formation in this case but also the

Fig. 3. The SRP profiles for the p-type Cz Si with the DZ (formed by 1100°C thermal heating for 5 h in flowing nitrogen) treated for 1 h by a HF hydrogen plasma at 250°C with subsequent annealing at 400°C. The peaks of the resistance curves correspond to the p–n junction location.

Fig. 4. The electron concentration due to the hydrogen enhanced TDs formation calculated according to Eqs. (1)–(4), (6)–(9) for the as-grown p-type Cz Si treated for 1 h by a hydrogen plasma at 250 °C with subsequent annealing at 400 °C.

Fig. 6. The electron concentration due to the hydrogen enhanced TDs formation calculated according to Eqs. (1)–(9) for the p-type Cz Si with the DZ (formed by 1100 °C thermal heating for 5 h) treated for 1 h by a hydrogen plasma at 250 °C with subsequent annealing at 400 °C.

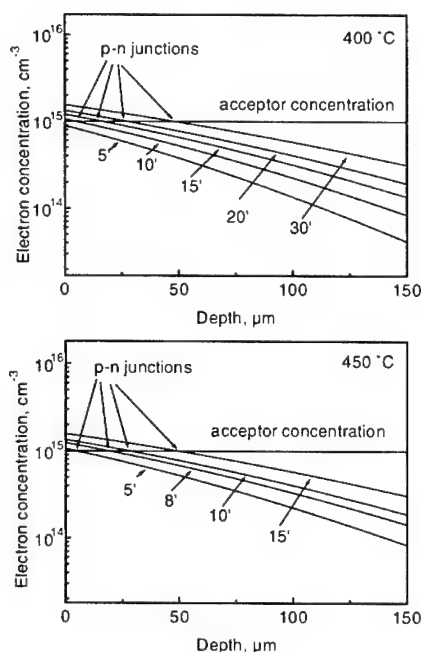

Fig. 5. The electron concentration due to the hydrogen enhanced TDs formation calculated according to Eqs. (1)–(4), (6)–(9) for the as-grown p-type Cz Si treated for 10 min by a hydrogen plasma at 400 °C with subsequent annealing at 400 °C and 450 °C.

oxygen precipitation during the DZ formation has to be taken into account.

5. Conclusions

The hydrogen enhanced TDs formation in the p-type Cz Si can be used for the low-temperature production of device structures: p–n junctions, p–n–p structures and

structures with gradient doping. This method of doping can be described numerically and can be used as an alternative low-cost, low-temperature one. A kinetic model for the analysis of the hydrogen enhanced TDs formation in the as-grown p-type Cz Si is developed and can be used for the simulation of the p–n junction location originated due to counter doping by the TDs. For the case of Cz Si with the DZ, this model has to be corrected. The oxygen precipitation during the DZ formation process has to be taken into account.

On defects created in 45 keV H[−]-implanted n-type Cz Si: a fluence dependence and isochronal annealing study

Prakash N.K. Deenapanray*

Department of Electronic Materials Engineering, Research School of Physical Sciences and Engineering, Australian National University, Canberra ACT 0200, Australia

Abstract

Five electron traps E1 ($E_C = 0.17$ eV), E2 ($E_C = 0.22$ eV), E3 ($E_C = 0.29$ eV), E4 ($E_C = 0.43$ eV), and E5 ($E_C = 0.50$ eV) were created in n-Si by 45 keV H[−] implantation. E1 (VO-centre) and E2 (V_2^{2+}) increased linearly with fluence in the range 5×10^{10} – 1×10^{12} cm^{−2}, while the hydrogen-related defects E3 (VO–H) and E5 showed a quadratic fluence dependence. E4 also exhibited a quadratic fluence dependence, which could be characteristic of overlapping traps, including VP, V_2^0 , VH, and V_2H . The ratio E3:E1 showed sign of saturation at the higher fluences, whereas E5:E2 increased monotonically with the increasing fluence. E3 and E5 increased with the annealing temperature at the expense of E1 and E2, respectively, up to 200°C, but without a one-to-one correlation. Two secondary defects E6 ($E_C = 0.20$ eV) and E7 ($E_C = 0.49$ eV), which we propose to be higher-order vacancy clusters, were observed above 350°C. © 2001 Elsevier Science B.V. Keywords: DLTS; Defects; Hydrogen; Isochronal annealing

1. Introduction

The interaction of H with deep levels in Si is a subject of both technological and scientific interest. Hydrogen can be introduced into the semiconductor material both intentionally and unintentionally through a host of ways, including growth, ion implantation, chemical cleaning, or exposure to a hydrogen plasma [1]. It is very mobile and exhibits a wide range of interactions with impurities and defects in crystalline semiconductors [2]. Over the past decade, much has been learned about the structure of hydrogen-related electron traps in Si. A deep level at $\sim E_C = 0.16$ eV has been identified as the H–C complex [3]. Due to the isoelectronic behaviour of substitutional C in crystalline Si, this level mainly reflects the electronic properties of the isolated hydrogen [4]. Defects E3 ($\sim E_C = 0.32$ eV) and E5 ($\sim E_C = 0.45$ eV) have also been related to hydrogen

complexes [5]. More recently, Laplace deep-level transient spectroscopy (DLTS) has been used in conjunction with EPR annealing data to identify E3 as the VO–H complex, as well as the acceptor levels of VH and V_2H in Si [6]. In general, no deep levels associated with the implanted species are observed by DLTS in room-temperature-bombarded Si, except for hydrogen. In this study, we report on the fluence dependence and isochronal annealing behaviour of defects, especially the H-related traps, introduced in n-Si by 45 keV H[−] implantation.

2. Experimental procedure

n-type Czochralski (Cz) Si(100) wafers with resistivity of 0.7–1.1 Ω cm were implanted at RT by 45 keV H[−] ions to fluences ranging from 5×10^{10} to 1×10^{12} cm^{−2}. The fluence rate was fixed at 1×10^{10} cm^{−2} s^{−1} for all implants. Isochronal annealing in the 150–600°C range was performed on samples implanted to 1×10^{11} cm^{−2} for 15 min under Ar flow. Following chemical cleaning, including a final dip in 5% HF, Au Schottky contacts

were fabricated on samples by resistive evaporation. DLTS was used to study the fluence dependence and isochronal annealing behaviour of hydrogen-induced defects. Reverse bias and filling pulse conditions were chosen such that the region extending between 0.35 and 0.6 μm of each sample was probed by DLTS.

3. Results and discussion

DLTS spectrum (a) in Fig. 1 was taken from a sample implanted with 45 keV H^- ions to a fluence of $1 \times 10^{11} \text{ cm}^{-2}$. Spectra (b–d) are from samples annealed at 150°C, 200°C, and 500°C, respectively. Hydrogen implantation created five electron traps E1 ($E_C = 0.17 \text{ eV}$), E2 ($E_C = 0.22 \text{ eV}$), E3 ($E_C = 0.29 \text{ eV}$), E4 ($E_C = 0.43 \text{ eV}$), and E5 ($E_C = 0.50 \text{ eV}$). In the n-type Si, single vacancies created by H interact with each other, dopant atoms (e.g. P) and interstitial oxygen (O_i) to form the divacancy (V_2), VP- and VO-centres. Defects E1, E2, and E4 correspond to the well-known VO-centres, $\text{V}_2^{2-/}$, and the superposition of the VP-centres and $\text{V}_2^{0/}$, respectively [7]. We will establish, in what follows, that E4 may also contain contributions from H-related defects. Since P and O_i are more efficient trapping centres for the single vacancies, they are produced in larger concentrations than V_2 [spectrum (a) in Fig. 1]. Interaction between implanted H and other defects produces E3 and E5 [5], with the former being the VO–H complex [6]. L  v  que et al. have recently proposed that E5 resulted from the interaction of H with V_2 [8]. The virtual nondetection of E4 in spectrum (c) and given that the VP-centre is thermally unstable above $\sim 180^\circ\text{C}$, reveals that defect E4 consisted mostly of VP-centres. More will be said about DLTS spectra (b–d) later.

Fig. 2(a) illustrates the fluence dependence for the introduction of electron traps in n-Si by 45 keV H-implantation. The VO-centre (E1) and $\text{V}_2^{2-/}$ (E2) are introduced linearly with ion fluence, albeit the latter is introduced in much lower concentrations. The linear fluence dependence of E2 shows that it is created as a primary event, and its lower concentration than E1 reveals that it has a higher energy formation threshold. Our results are consistent with a previous study using 200 keV H-implantation of Si in the fluence range from 3×10^9 to $1 \times 10^{11} \text{ cm}^{-2}$ [9]. On the other hand, E3 (VO–H) and E5 exhibit a quadratic dependence on hydrogen fluence. A near-quadratic dependence of the VO–H centre was also reported in Ref. [9] for fluences $< 5 \times 10^{10} \text{ cm}^{-2}$. The quadratic dependence clearly shows that the introduction rates of E3 and E5 become increasingly more favourable at the higher fluences when both H and other primary defects, such as VO, become more abundant. In contrast to the linear fluence dependence of the level at $E_C = 0.41 \text{ eV}$ reported in

Fig. 1. DLTS spectra from (a) as-implanted n-Si, and samples annealed for 15 min at: (b) 150°C, (c) 200°C, and (d) 500°C. All samples were implanted with 45 keV H^- ions to a fluence of $1 \times 10^{11} \text{ cm}^{-2}$ at room temperature.

Fig. 2. Fluence dependence of (a) creation of E1 (VO), E2 ($\text{V}_2^{2-/}$), E3 (VO–H), E4, and E5, and (b) ratio E3:E1 and E5:E2.

Ref. [9], results shown in Fig. 2(a) reveal a quadratic dependence of E4 on fluence similar to E3 and E5. Assuming that E4 was the superposition of the primary defects VP and $\text{V}_2^{0/}$, one would indeed expect a linear fluence dependence of E4. Bonde Nielsen et al. have recently shown that the activation enthalpies of $\text{VH}^{0/-}$ and $\text{V}_2\text{H}^{0/-}$ were 0.443 and $\sim 0.43 \text{ eV}$, respectively, which are practically indistinguishable from those for VP and $\text{V}_2^{0/}$ [6]. We, therefore, propose that the

Fig. 3. Isochronal annealing behaviour of implantation-induced defects E1 (VO), E3 (VO-H), and E5, and secondary defects E6 and E7.

quadratic dependence of E4 on fluence could be due to the presence of the overlapping defect VH. It is pointed out here that annealing at 200°C [spectrum (c) in Fig. 1] should remove almost all of VH [6]. Furthermore, the larger fluences used in this study may account for the discrepancy between the results presented here and in Ref. [9].

Further insight is obtained on the introduction of E3 (VO-H) and E5 by comparing their intensities with respect to those of E1 (VO) and E2 (V_2^+), respectively, as shown in Fig. 2(b). The ratio [VO-H]/[VO] increases initially but tends towards saturation at the higher fluences. Such a behaviour may be characteristic of the VO-H complex because of both the limited supply of O in samples and the formation of VO-H₂, which is electrically inactive [6], at the higher fluences. In contrast, the ratio [E5]/[E2] increases monotonically with the increasing hydrogen fluence. Assuming the proposed relationship between E5 and V_2 [8], we speculate that the hydrogenation of V_2 is enhanced at the higher fluences when more V_2 are created in both direct events and combination of single vacancies (O trapping sites having been consumed).

We now turn to the isochronal annealing of defects as shown in Fig. 3. We have not measured the annealing of E2 because of the large uncertainty in measuring its peak intensity. The initial increase in E3 below 200°C does not correlate linearly with the decrease in E1. The relatively larger decrease in E1 could be attributed to the removal of an overlapping bistable C_iC_k pair [10], together with the further passivation of VO by H released from complexes with low thermal stability, such as H-C and VH. Both VO and VO-H are removed above 200°C. A comparison of spectra (a-c) in Fig. 1 clearly shows the annealing of V_2^+ . The removal of E2 is accompanied by the simultaneous increase in E5,

which establishes a relationship between E2 and E5 [8]. The removal of vacancy-related defects E1-E5 above 350°C is accompanied by the formation of secondary defects E6 ($E_c = 0.20$ eV) and E7 ($E_c = 0.49$ eV). The similar annealing behaviour of E6 and E7 suggests that they may be two charge states of the same defect. We have previously correlated the creation of similar defects in both MeV alpha-particle irradiated and Si-implanted n-type Si samples annealed above 300°C with the disappearance of V_2 [11,12], and concluded that they were higher-order vacancy complexes.

4. Conclusions

In summary, we have investigated the fluence dependence and isochronal annealing behaviour of defects created in 45 keV H-implanted n-Si. VO and V_2^+ exhibited linear fluence dependencies, whereas each of VO-H, E4, and E5 showed a quadratic dependence on fluence. In addition to the VP-centre and V_2^0 , the VH complex could also be a component of E4. The ratio [E3]/[E1] showed saturation at the higher fluences typical of the limited supply of O and the further passivation of VO-H into electrically neutral VO-H₂. The initial increase of VO-H below 200°C could be due to the hydrogenation of VO upon release of H from less-thermally stable defects, such as H-C and VH. Annealing experiments have shown the close correlation between E5 and V_2 , as well as the creation of two higher-order vacancy complexes, E6 and E7, above 350°C. E6 and E7 could be the same defect but with different charge states.

DLTS study of defects in hydrogen plasma treated p-type silicon

L. Wu*, A.W.R. Leitch

Department of Physics, University of Port Elizabeth, PO Box 1600, Port Elizabeth 6000, South Africa

Abstract

A deep level transient spectroscopy (DLTS) study of defects found in float-zone p-type silicon exposed to a DC hydrogen plasma is reported. DLTS measurements of these samples revealed three deep levels. Two of the levels are broad, with $E_T - E_V$ in the range 0.34–0.39 eV (H2) and 0.40–0.44 eV (H3); these appear as bands in the Arrhenius plot. The third level has an activation energy of 0.09 eV (H1). The variations in the capture cross-sections of H2 and H3 are believed to be strain-related. The concentration of H3 exceeds the other two levels and decreases rapidly into the samples with $\sim 10^{15} \text{ cm}^{-3}$ at a depth of 0.20 μm . H3 is tentatively ascribed to an extended defect. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Deep level transient spectroscopy; Silicon; Defects; Hydrogen

1. Introduction

Hydrogen is one of the most important impurities in silicon and is often used in the passivation of defect and other impurity states. It is commonly introduced into silicon via exposure to a hydrogen plasma. However, exposure to this plasma environment also creates defects in the material such as hydrogen platelets, H_2 molecules, point defects, etc. [1]. The damage caused by plasma is well known to be electrically active, which can be detrimental to the devices fabricated from the material.

There have been a few reports in the literature [2–6] on the electrical characteristics of defects induced through various plasma techniques, the majority of which were on n-type material. Hwang et al. [3] were amongst the first to detect deep levels in oxygen-precipitated p-type Cz-Si after hydrogen plasma processing; the deep levels were believed to be caused by the energetic ions in the plasma. Both Nam et al. [5] and Henry et al. [6] assigned the deep levels they found in their Cz material to some type of extended defect or possibly platelets.

There is considerable variation in the deep levels reported since the experiments were performed exclusively on Czochralski silicon (with the exception of Ref. [4], where the material type was not mentioned). In this material, the contribution of oxygen, such as thermal donors and oxygen precipitates, towards the formation of the defects cannot be excluded. For this reason, float-zone silicon was employed in this work and deep level transient spectroscopy (DLTS) was used to detect its electrical characteristics.

2. Experimental details

Boron-doped 0.1–0.6 Ωcm float-zone silicon wafers have been used in this study. Hydrogen was introduced into the samples in a remote DC hydrogen plasma with a voltage of 600 V applied across the plates. The samples were held at a temperature of 150°C, and a reverse bias was applied which accelerated the ions into the sample. These conditions were found to cause the passivation of the B-acceptors by the hydrogen through the formation of electrically neutral B–H complexes [7].

The samples were subsequently annealed at 300°C in an inert atmosphere after plasma exposure to restore the

*Corresponding author. Fax: +27-41-504-2573.

E-mail address: phblw@upe.ac.za (L. Wu).

dopant profile to its original state. Schottky barrier diodes (SBDs) were fabricated with Al Schottky contacts and Ga–In eutectic ohmic contacts. DLTS spectra were collected in the temperature range 40–320 K and the rate window was set using a lock-in amplifier. The activation energies ($E_T - E_V$) and apparent hole capture cross-sections σ_p were determined from the Arrhenius plot using the lock-in frequencies between 1 and 460 Hz. Reference samples underwent similar treatments with a zero plate voltage in the plasma system (i.e. no plasma exposure).

3. Results

DLTS spectra from different SBDs passivated under identical conditions are shown in Fig. 1. It was not possible to scan samples A and B to higher temperatures since leakage current became dominant at higher temperatures. It is evident from Fig. 1 that the plasma introduced a significant concentration of defects into silicon, which were all found to be within 0.3 μm of the semiconductor surface. Not all the DLTS peaks were present in the spectrum of each SBD. These irregular occurrences are ascribed to the non-uniform plasma conditions resulting in an inhomogeneous defect distribution. These peaks could not have originated from surface-related defects since we did not find any peaks in the reference sample. Three deep level traps could be identified; they are labelled H1, H2 and H3, with the latter being the dominant peak.

Fig. 1. DLTS spectra of selected SBDs taken at a frequency of 46 Hz ($\tau = 9.35$ ms) under a reverse bias of -1 V, filling pulse of $+1.3$ V and pulse width of 0.5 ms.

Fig. 2. Arrhenius plot of all deep levels found in plasma-exposed samples (markers). Included are data from Ref. [9] (dashed line), Ref. [11] (dotted line), Ref. [10] (solid line) and Ref. [6] (dot-dash line).

Table 1

Range of defect energy levels and effective capture cross-sections obtained for the defects found in Fig. 1

	$E_T - E_V$ (eV)	σ_p (cm^{-2})
H1	0.09	$2\text{E-}15$ – $7\text{E-}15$
H2	0.34–0.39	$2\text{E-}16$ – $6\text{E-}15$
H3	0.40–0.44	$1\text{E-}17$ – $5\text{E-}17$

Fig. 2 shows the Arrhenius plots of all the defects found in the plasma exposed material. Defects found in literature with similar trap signatures are also plotted in Fig. 2. It is seen that the Arrhenius data of the deep levels lie in three distinct bands. Each band is attributed to a single defect since the slopes, i.e. activation energy, are nearly identical. These defects are thought to exist in a varying strain field, thus affecting the hole capture rate and subsequently σ_p . Table 1 lists the ranges in which the defect energy levels and apparent capture cross-sections lie.

The average concentration of H1 was determined as $2 \times 10^{13} \text{ cm}^{-3}$ and typical concentration profiles of H2 and H3 are plotted in Fig. 3. It should be noted that the effect of the Debye free carrier tail was not taken into consideration during the calculation of the defect depth profiles. There is an extremely high concentration of defects near the surface (H3) that decreases with a near-exponential behaviour into the plasma-exposed material. A reasonable correlation exists between the profiles of H2 and H3 in the range 0.21–0.24 μm ; their creation likely arose from the same source, i.e. plasma damage and/or is hydrogen related. Experimental constraints due to the lower capacitance (and thus larger depletion width) at the temperature of the H2 peak maximum limited the start of the defect profiling to a depth of

Fig. 3. Concentration profiles of the H2 and H3 deep levels.

0.21 μm . It is quite possible that the profile of H2 has the same trend as H3 before 0.21 μm .

The defect H3 exhibited anomalous behaviour during reverse bias annealing (RBA) at temperatures higher than 320 K. Upon RBA, the peak intensity decreased during the first 30 min after which it increased slightly in intensity. A zero bias anneal (ZBA) at 347 K restored the peak height to its original value. No new DLTS peak was detected during the annealing. Furthermore, there was no measurable change in the trap profile before and after RBA. It is believed that a complex reaction takes place during the RBA with at least two competing processes. Further investigations are continuing in this area.

4. Discussion

The likelihood of H1 (0.09 eV) being the FeB complex (known to occur at 0.10 eV [12]) was discounted given that no peak was seen in the reference sample, implying that there was no Fe contamination during the processing. A bistable $C_i - C_s$ defect, in which one of the configurations has the same activation energy as H1, was detected in electron-irradiated material [8]. Since H1 did not exhibit the described bistable behaviour, it therefore could not be identified with the carbon-related defect. However, excellent correspondence was found with an unidentified defect formed in dislocation-induced silicon [9], which is seen in Fig. 2. H1 is therefore ascribed to an intrinsic defect.

The trap signatures of both H2 and H3 varied from diode to diode. Although the activation energies change slightly, the more noteworthy feature is the considerable variation in the capture cross-sections. It is believed that the defects exist in a strain field, where the efficient capture of holes could be affected by the surrounding matrix.

The trap signature of H2 agrees relatively well with a defect ($E_T = 0.38$ eV, $\sigma_p = 1 \times 10^{-15} \text{ cm}^2$) formed during electron-beam deposition [10], while Ref. [11] also detected a defect with similar energy and capture cross-section ($E_T = 0.41$ eV, $\sigma_p = 8 \times 10^{-15} \text{ cm}^2$) in thermally quenched silicon (see Fig. 2). However, they did not observe any significant variation in the capture cross-section.

We now consider the H3 level. An additional factor contributing to the variation of its capture cross-section is the shifting of the peak maximum towards higher temperature during annealing. This shifting occurred for both zero bias and reverse bias anneals. For a lock-in frequency of 46 Hz, the temperature shifted from 286 to 301 K, where it then stabilised. The peak intensity also increased after ZBA. The broad nature of the H3 peak, coupled with its temperature behaviour, leads us to suggest that it may contain multiple peaks arising from a band of defects with closely spaced energy levels; during annealing the relative population of the various states could change, thereby shifting the position of the effective peak maximum. This might further imply that it is an extended defect. Henry et al. [6] detected a similar trap level at $E_V + 0.48$ eV (plotted in Fig. 2) after exposing Cz-Si to a D_2 plasma during reactive ion etching. However, they did not report any metastability or shifting of σ_p .

5. Conclusions

Three deep levels were detected in p-type float-zone silicon after exposure to hydrogen plasma, with a high concentration of defects near the surface. Two of the levels have variable capture cross-sections which could be attributed to the strained matrix around the defects and possibly extended defects. Trap signs similar to these three levels were found in either plasma-exposed electron irradiation or dislocation-induced Si.

Abstract

Local mode spectroscopy and ab initio modelling are used to investigate two trigonal defects found in carbon-rich Si into which H had been in-diffused. Isotopic shifts with D and ^{13}C are reported along with the effect of uniaxial stress. Ab initio modelling studies suggest that the two defects are two forms of the CH_2^* complex where one of the two hydrogen atoms lies at an anti-bonding site attached to C or Si, respectively. The two structures are nearly degenerate and possess vibrational modes in good agreement with those observed. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Hydrogen and carbon are common interstitial and substitutional impurities, respectively, in silicon [1,2]. The single hydrogen defect is highly mobile and is easily trapped by impurities and lattice defects. One prominent defect found in proton implanted Si, or Si containing H which has been e-irradiated, is the trigonal H_2^* centre

which contains two inequivalent H atoms. One H atom lies at a bond centred site and the other at a neighbouring anti-bonding site [3]. It might be expected that dilated Si–Si bonds due to the strain field surrounding substitutional carbon atoms will be trapping sites for H. However, the greater binding energy of H with C rather than Si [4] suggests that H will attach directly to C. Examples of defects where H bonds to Si rather than C are given in Ref. [5], while Ref. [6] exemplifies the second defect type. In other cases, it is not clear which type is present [7,8].

Recently, several local vibrational modes (LVMs) were observed in carbon-rich Si samples treated in a hydrogen ambient at high temperatures [9–12]. Some arise from a trigonal complex containing one carbon and two hydrogen atoms [9]. The LVMs of this defect, labelled $(\text{C}-H_2^*)_2$, are given in Table 1. Following previous theoretical results [13], it was suggested that

Fig. 1. The two degenerate C_{3v} structures for CH_2^* : (a) $\text{H}_{ab}\text{CH}_b\text{Si}$ and (b) $\text{H}_{ab}\text{SiH}_b\text{C}$. Relevant bond lengths and angles are shown where appropriate.

this complex is a H_2^* defect trapped near C. There are two possible trigonal forms of the centre where the anti-bonding sited H is bonded to Si or C (Fig. 1). The observed modes are somewhat more stable than H_2^* , which anneals at $\sim 200^\circ\text{C}$ [3], as they survive until $\sim 400^\circ\text{C}$ [9]. We show in the present work that there is another set of LVM absorption lines, which is related to the other form of C-H_2^* centre, labelled $(\text{C-H}_2^*)_1$. These

assignments are based on the analysis of positions, shifts, and splitting of LVM bands with different isotopic combinations (H, D, ^{12}C , ^{13}C). Application of uniaxial stress and comparison with ab initio modelling further strengthen the assignments.

2. Experimental and theoretical details

Samples for this study were prepared from lightly doped n-type and p-type float-zone-grown Si crystals with different carbon concentrations in the range $(1.5\text{--}3.0)\times 10^{17}\text{ cm}^{-3}$. A few samples were prepared from a crystal enriched with ^{13}C isotopes to about $8\times 10^{17}\text{ cm}^{-3}$. Hydrogen and/or deuterium was introduced by a heat treatment at $1250\text{--}1350^\circ\text{C}$ for 30 min or 1 h in a H_2 (D_2) gas ambient at a gas pressure of about 1.0 or 1.5 atm, followed by a quench. The isochronal annealing was carried out in an argon atmosphere in temperature steps of 25°C in the range of $100\text{--}450^\circ\text{C}$, for 30 min at each temperature. The thickness of the samples was in most cases about 6 mm. The samples used for the uniaxial stress measurements had dimensions $10\times 3\times 2\text{ mm}^3$. Optical absorption spectra were measured by Fourier transform infrared (FT-IR) spectrometers at

Fig. 2. (a) Difference absorption spectra measured at 10 K with a resolution 0.5 cm^{-1} for (1) Si : ^{12}C samples doped with hydrogen and deuterium and (2) Si : ^{13}C samples doped with hydrogen and deuterium (spectra of D-doped sample were subtracted from those of H-doped ones); (b) details of infrared absorption spectra, measured at 10 K with a resolution 0.1 cm^{-1} , on ^{12}C - and ^{13}C -rich Fz-Si samples, which were doped with hydrogen, deuterium and H + D mixture (50% + 50%). Multiplication factors for different parts of the spectra are indicated. All the samples were treated in H(D) gas ambient at 1350°C for 30 min with a gas pressure of about 1.5 atm.

$\sim 10 \text{ K}$. The spectral resolution varied from 0.1 to 0.5 cm^{-1} .

The properties of C-H_2^* defects in silicon, were investigated by a local density-functional technique as implemented in the AIMPRO code [14]. The defects were inserted into 64 atom supercells and a 2^3 Monkhorst-Pack k-point sampling scheme used to integrate over the band structure [15]. The basis consisted of independent s- and p-Gaussian orbitals, with four different exponents, sited at each Si atom, four at the carbon atom, and three at the H atom. In addition, a single set of s- and p-Gaussian functions was placed between every neighbouring pair of atoms. The Hartree and Perdew-Zunger [16] exchange-correlation energies were calculated using a plane-wave intermediate fit with an energy cut-off of 200 Ry. All atoms were allowed to relax by a conjugate gradient method. The second derivatives of the energy were found for the atoms of the defects and their immediate neighbours, allowing vibrational modes to be calculated from the dynamical matrix, with additional entries in the matrix constructed from a Musgrave-Pople potential (further details are given in Ref. [17]).

3. Results

Among the many sharp absorption lines observed in the frequency ranges 660–690, 790–820, 1920–1960, 2120–2230, and $2680\text{--}2950 \text{ cm}^{-1}$ [9–12], lines at 2210.4 cm^{-1} and 665.3 cm^{-1} are of particular interest in the present work (Fig. 2). A clear linear correlation was found between the intensities of these lines in

Fig. 3. Isochronal annealing temperature dependence of the integrated absorption intensity of the bands at 665.3 and 2210.4 cm^{-1} in a ^{12}C -rich Fz-Si sample which was treated in H_2 gas at 1350°C for 30 min. IR absorption measurements were carried out at 10 K with a resolution 0.5 cm^{-1} .

different samples and the lines were found to have an identical annealing behaviour as illustrated in Fig. 3. This suggests that they originate from the same defect. The positions of the lines of this complex, labelled $(\text{C-H}_2^*)_1$, in ^{12}C , ^{13}C , H and D material, as well as material containing a mixture of H and D, are given in Table 1.

The shift of the 665.3 cm^{-1} line with ^{13}C and D, as well as its splitting in the mixed H, D case, demonstrates that the defect contains one C and two H atoms. Similar conclusions arise from inspection of the shifts of the

Fig. 4. The effect of uniaxial stress on the 2210.4 cm^{-1} mode. **F** denotes stress axis and **E** the electric-field direction of the incident light.

2210.4 cm^{-1} line except that its shift with ^{13}C is negligible. This implies that the H involved in the mode is not bonded directly to C and the 2210.4 cm^{-1} line is due to a stretch mode of Si–H. The 665.3 cm^{-1} mode is assigned to a perturbed mode of substitutional carbon at 607 cm^{-1} .

Fig. 4 shows the effect of uniaxial stress on the 2210.4 cm^{-1} mode. The splitting pattern is found to be consistent with the assignment to an A_1 mode of a defect possessing trigonal symmetry.

All combinations of pairs of hydrogen atoms at bond-centre and anti-bonding sites within one and two neighbouring sites of substitutional carbon were structurally relaxed. Two degenerate structures with C_{3v} symmetry were found to possess the lowest energy by at least $\sim 0.4 \text{ eV}$. These structures are similar to the H_2^* defect [3] and are shown in Fig. 1. The calculated LVMS are given in Table 1. The calculated Si–H stretch mode in $\text{H}_{ab}\text{CH}_{bc}\text{Si}$ (Fig. 1a) at 2172 cm^{-1} is close to the observed mode at 2210.4 cm^{-1} . There are undetected C–H stretch and bend modes at 2664.5 and 1018.4 cm^{-1} , respectively. We assign the observed mode at 665.3 cm^{-1} to the E (C–Si) mode at the same frequency. The isotopic shifts are in good agreement with the experimental ones. Accordingly, we assign the $(\text{C–H}_2^*)_1$ defect to $\text{H}_{ab}\text{CH}_{bc}\text{Si}$.

We now turn to the previously reported modes of $(\text{C–H}_2^*)_2$ [9]. These are in good agreement with the calculated modes of $\text{H}_{ab}\text{SiH}_{bc}\text{C}$ shown in Fig. 1b. In particular, the C–H and Si–H stretch modes observed at 2752 and 1922 cm^{-1} are close to the calculated ones at 2736 and 1923 cm^{-1} . The Si–H wag mode at 792 is close to the calculated one at 812 cm^{-1} . Similarly, there is good agreement with the isotopic shifts. Accordingly, we assign the $(\text{C–H}_2^*)_2$ defect to $\text{H}_{ab}\text{SiH}_{bc}\text{C}$.

Finally, for completeness, the stress-energy B -tensor for both forms of H_2^* were calculated. These tensors have not yet been experimentally measured. The tensors are evaluated directly by first relaxing the volume of the cubic cell and then calculating $\partial E/\partial \epsilon_{ij}$ with Cartesian

axes, where ϵ_{ij} is the strain [14]. For trigonal defects, the tensor has principal values $\frac{1}{2}B_{11} = -B_{22} = -B_{33}$ with the principle directions $\langle 111 \rangle$ (along the C_3 axis), $\langle 1\bar{1}0 \rangle$ and $\langle 11\bar{2} \rangle$. The values of B_{11} for $\text{H}_{ab}\text{CH}_{bc}\text{Si}$ and $\text{H}_{ab}\text{SiH}_{bc}\text{C}$ were found to be 7.69 and 11.15 eV per unit strain. The fractional volume changes for the defects in a 64 atom cubic cell were found to be 0.2% and 0.3% , respectively, i.e., $\Delta V/V_0 = 64 \times 0.2\%$. So the volume change caused by the defect is just $0.1 \times V_0$ where V_0 is the volume of Si atom (defined as $a_0^3/8$).

4. Conclusions

Local mode spectroscopy and ab initio modelling has identified two LVM bands observed at 2210.4 and 2752.3 with H stretch modes of two forms of C–H_2^* defects where H lies anti-bonded to C and Si, respectively. Several other modes are observed in each defect and related to particular atomic displacements.

The strange behavior of interstitial H_2 molecules in Si and GaAs

S.K. Estreicher^{a,*}, J.L. McAfee^a, P.A. Fedders^b, J.M. Pruneda^c, P. Ordejón^d^a Physics Department, Texas Tech University, Lubbock, TX 79409-1051, USA^b Physics Department, Washington University, St. Louis, MO 63130, USA^c Departamento de Física, Universidad de Oviedo, E-33007 Oviedo, Spain^d Institut de Ciència de Materials, CSIC, UAB, E-08193 Bellaterra, Barcelona, Spain

Abstract

Interstitial H_2 molecules have been observed in GaAs and in Si and behave very differently in the two hosts. In GaAs, H_2 has rotational symmetry, a stretch frequency close to the free-molecule value, and the Raman spectrum exhibits the expected ortho/para splitting. In Si, the symmetry is C_1 , the stretch frequency is about 550 cm^{-1} lower than that of free H_2 , and no ortho/para splitting is seen. In this paper, we use ab-initio molecular-dynamics simulations (SIESTA) to calculate the vibrational frequencies of H_2 using linear response theory as well as the velocity–velocity autocorrelation function. We also study the interactions between H_2 and O_i as well as paramagnetic H in Si. Based on these calculations and arguments about the formation process of H_2 , we argue that rapid $H_2 \rightleftharpoons H_T^0$ interactions are a possible candidate to explain the absence of ortho- H_2 in Si. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Molecular dynamics; Hydrogen; Silicon; Gallium arsenide

1. Introduction

The interstitial H_2 molecule in GaAs has been observed by Raman spectroscopy [1] and behaves like a near-free molecule. At 77 K, the Raman lines at 3926 and 3934 cm^{-1} are close to the free H_2 line (4160 cm^{-1}) and show an 8 cm^{-1} ortho/para splitting with 3:1 ratio. This implies that only the $j=0$ and 1 quantum rotational states are occupied and, therefore, that the molecule is spherically symmetric. This is confirmed by uniaxial stress experiments [2] which show no line splitting under $[001]$, $[110]$, or $[111]$ stress. At room temperature, the H_2 , HD, and D_2 lines are at 3911 , 3429 , and 2827 cm^{-1} , respectively. The molecule has not been seen by infrared (IR) absorption spectroscopy. The isotope shifts and relative amplitudes are about as one would expect. First-principles calculations [3–7] predict that the center of mass (CM) of H_2 is at the tetrahedral interstitial site with four Ga nearest neighbors (NNs), T_{Ga} , and that the molecule is a nearly free rotator. The

calculated frequencies of H_2 are close to the measured ones, 3704 cm^{-1} in Ref. [6] and 3824 cm^{-1} in Ref. [7].

The behavior of H_2 in Si is different. The molecule is not just Raman [8] but also IR [9] active, the local vibrational mode (LVM) is much lower, just above 3600 cm^{-1} , and no ortho–para splitting is seen. Uniaxial stress experiments [10] imply C_1 symmetry. A single HD line is seen, but shifted relative to its expected position [10] and with a very low amplitude [11]. The IR lines are extremely sharp. Some fifteen theoretical papers (see Ref. [12] for details and references) have been published on H_2 in Si. Most authors find that the stretch frequency is substantially reduced relative to that of the free molecule, as observed. However, the CM is almost always found to be at the T site where the molecule should be a nearly free rotator. These predictions conflict with several key experimental data, notably the low symmetry, IR activity, and absence of ortho/para splitting.

Recent ab-initio molecular-dynamics (MD) simulations [12] of H_2 have shown that at $T > 0\text{ K}$ in Si, the average position of the CM moves off the T site along $\langle 100 \rangle$ and shifts off that axis under uniaxial stress. Further, the molecule moves within its tetrahedral cage

*Corresponding author. Tel.: +1-806-742-3723; fax: +1-806-742-1182.

E-mail address: stefan.estreicher@ttu.edu (S.K. Estreicher).

extremely fast. The amplitude of its oscillation changes abruptly as the oscillator exchanges energy with the host crystal. Similar MD simulations in GaAs show no such motion of the CM. This host is partly ionic and, at the T_{Ga} site, H_2 is surrounded by four positively charged Ga NNs and six negatively charged As NNs. The resulting electrostatic potential prevents the rapid motion of the molecule.

Our calculations are done using the SIESTA code [13,14] as described in Ref. [12]. These are classical MD simulations in which the electronic problem is solved at the ab-initio level within density-functional theory. The electronic basis sets consist of numerical linear combinations of atomic orbitals and vary from single zeta (SZ: one s and three p per Si for example) to double zeta (DZ) with polarization (P) functions (two sets of s and p and one set of d per Si for example). For the purpose of calculating vibrational frequencies, the host crystal is represented by periodic supercells of 64 Si atoms and the k -point sampling is reduced to the Γ -point.

2. Vibrational frequencies

They are obtained from two techniques. A *static* ($T = 0\text{ K}$) perturbative approach, based on linear response theory and discussed in Ref. [15], extracts the dynamical matrix analytically from the derivatives of the density matrix relative to atomic displacements. Specific LVMs are also calculated *dynamically* from the Fourier transform of the velocity–velocity autocorrelation function [16,17]. Here, the components of the velocities of each H atom along the H–H bond are saved at every time-step as the molecule moves around its cage and interacts with the Si host crystal. In the present work, we allow the system to evolve for 12,000 time-steps at $T = 30\text{ K}$.

The measured (gas phase) frequencies of *free* H_2 , HD, and D_2 are 4161, 3632, and 2994 cm^{-1} , respectively. The calculated values are 4185, 3625, and 2960 cm^{-1} with linear response theory and 4137, 3628, and 2957 cm^{-1} with the v – v autocorrelation function and a DZP basis set. Note that the dynamically calculated frequencies are within 1% of the experimental values.

In GaAs, we calculated the frequencies so far only with the linear response theory. For interstitial H_2 , HD, and D_2 at the T_{Ga} site, the calculated (measured [1]) numbers are 3757 (3911), 3259 (3429), and $2657 (2957)\text{ cm}^{-1}$, respectively. For H_2 at the T_{As} site, the numbers are 3770, 3272, and 2667 cm^{-1} , respectively (H_2 has yet to be observed at the T_{As} site in GaAs). We find the energy difference between these two sites to be small, 0.08 eV.

In Si, the measured [9] frequencies of H_2 , HD, and D_2 are 3618, 3265, and 2643 cm^{-1} , respectively. Our static calculations predict 3550, 3082, and 2511 cm^{-1} , respec-

tively. The dynamic frequencies vary with the basis set used, most likely because of the rapid interactions between H_2 and the Si–Si bonds around its cage. A number of calculations are still under way and the results presented here are preliminary. With 12,000 time-steps at 30 K, a SZ basis set on the Si atoms, and a DZP basis set on the H atoms, we get for H_2 , HD, and D_2 3745, 3261, and 2649 cm^{-1} , respectively. While the D_2 and HD frequencies are very close to the IR values measured at 10 K (only +6 and -4 cm^{-1} off experiment, respectively), the H_2 number is off by 138 cm^{-1} ! Partial results with other basis sets also show shifts of the H_2 mode relative to experiment mode quite different from the shifts of D_2 and HD. This could be caused by the size of the time-step (0.2 fs), insufficient basis sets or total simulation times, or some quantum effect experienced by H_2 but not by the heavier HD or D_2 .

The substantial reduction ($\sim 550\text{ cm}^{-1}$) of the H_2 line in Si relative to free H_2 is predicted in most static calculations. It is in large part caused by the electron affinity of the four Si NNs and six second-NNs of H_2 at the T site. The calculated Mulliken charges [12] at 0 K show that each of these 10 Si atoms grabs a little electron density from H_2 which ends up slightly positively charged. This weakens the H–H bond, stretches the molecule, and causes a sharp drop in the frequency. No comparable delocalization of the molecular wavefunction occurs for H_2 in GaAs, which is surrounded by four positively charged Ga NNs and six negatively charged As NNs.

3. Interactions with impurities

H_2 molecules in Si have been observed [11] to trap in the vicinity of interstitial oxygen (O_i) with a binding energy of $0.26 \pm 0.02\text{ eV}$. Two distinct $\{\text{H}_2, \text{O}_i\}$ centers are formed. We performed geometry optimizations for numerous a priori possible configurations of H_2 near O_i in the 64 host-atoms cell, with a DZP basis set and a $2 \times 2 \times 2\ k$ points mesh, and found two configurations (Figs 1 and 2). The first, with binding energy 0.36 eV, has H_2 near a T site NN to O_i and the second, with binding energy 0.19 eV, has the molecule near a T site along the Si– O_i –Si bond.

We also calculated the binding energy of H_T^0 , neutral tetrahedral interstitial hydrogen, near H_2 . The energy gain for H_T^0 and H_2 at adjacent T sites relative to infinitely far apart is 0.16 eV (0.12 eV with H_T^0 and H_2 at second NN T sites).

4. Formation of H_2 in Si and ortho-to-para transition

The absence of distinct ortho- and para- H_2 lines in Si is very puzzling. At or below room temperature, free or

nearly free H_2 molecules have well-separated rotational states and only $j = 0$ and $j = 1$ are occupied. The latter is odd and three even combinations of spins are allowed: $\uparrow\uparrow$, $\uparrow\downarrow + \downarrow\uparrow$, or $\downarrow\downarrow$. The former is even, implying that an odd combination of nuclear spins is realized: $\uparrow\downarrow - \downarrow\uparrow$. This results in the well-known *o*- H_2 and *p*- H_2 lines with 3:1 intensity ratio. These lines are clearly visible in the case of H_2 in GaAs but not in Si. This can be explained in one of the two ways: (1) a hindering potential mixes the rotational j -states, a possibility suggested by Stoneham [18], and (2) the molecule is nearly free and some efficient mechanism flips the proton spins. Ortho-to-para transitions are typically induced by magnetic field gradients. Our MD simulations and the calculations of other authors suggest that H_2 in Si is a nearly free rotator, and dynamic runs show that the

Fig. 1. Calculated vibrational frequencies of free H_2 , HD, and D_2 from the $r-r$ autocorrelation function. This is a 12,000 time-steps run at 30 K. The gas phase measured values are 4161, 3632, and 2994 cm^{-1} , respectively. Note that the calculated values are within 0.2–1.2% of the measured ones and that the isotope substitutions show the observed anharmonic shifts.

molecule moves extremely fast within its tetrahedral cage. Thus, we consider the latter possibility. The rapid motion of H_2 implies that it will experience a magnetic field gradient provided that a magnetic moment is nearby.

We reject ^{29}Si , the only Si isotope with a nuclear spin, as it is less than 5% abundant and has a very small magnetic moment: the ortho-to-para transition would require very long times. Raman spectra of samples kept at room temperature for two years after the plasma exposure still show the H_2 line with no ortho/para splitting [19]. Months of interactions of H_2 with ^{29}Si have failed to establish a Boltzman distribution of *o*- H_2 and *p*- H_2 . We also reject interactions between nearby *o*- H_2 molecules during the quench. Such interactions result [20] in ortho-to-para transitions in a-Si:H, but the measured rate constant 0.01 h^{-1} is far too low to explain the c-Si data. Further, no magnetic impurity is present in sufficient concentration in all the Si samples in which H_2 has been observed, except hydrogen itself. We are thus led to propose that *paramagnetic* hydrogen, with a magnetic moment arising from an electronic spin (~ 2000 times larger than a nuclear moment), is the culprit.

Hydrogen penetrates into Si in atomic form. This is obvious in plasma-exposed samples [8]. In samples hydrogenated in a gas at high temperatures, the concentration of hydrogen varies roughly as the square root of the gas partial pressure [21]. Thus, H_2 dissociates at the surface, H penetrates into the crystal in atomic form, and interstitial H_2 molecules form during the quench starting with atomic hydrogen, that is any combination of H_{BC}^+ , H_{BC}^0 , H_T^0 , and/or H_T^- .

We rule out the interactions between identically charged species since they involve a long-range repulsion. In p-type material, H_{BC}^+ is most likely to trap at B^- and form {H, B} pairs, which are observed. H_{BC}^+ is a very

Fig. 2. The two configurations of H_2 near O_i in Si. The most stable one is at left, with 0.36 eV binding energy, and a metastable one at right, with 0.19 eV.

strong IR center which is never seen in the samples containing H_2 . We also rule out the process $H_{BC}^+ + H_T^- \rightarrow H_2$ because this would necessarily lead to the formation of some H_2^* , the IR intensity of which is very much larger than that of H_2 . Even tiny amounts of H_2^* would be clearly visible in the spectra. For this reason, any H_2 formation process involving H_{BC} can be ruled out. Thus, we are left with $H_T^0 + H_T^0 \rightarrow H_2$. The metastable H_T^0 species is not present in any meaningful concentration in equilibrium. However, its contribution during the dynamic process while H_2 molecules form, cannot be ruled out. There is indirect evidence [22,23] that H_T^0 diffuses extremely fast. Our calculations of its activation energy for diffusion, 0.06–0.15 eV (to be corrected downward by the zero-point energy) makes it an extremely mobile species.

As H_T^0 s precipitate during the quench, most form H_2 molecules, but some fail to find a partner. They diffuse very rapidly in the crystal, trapping momentarily at H_2 s (see the binding energies above), thus generating large magnetic field gradients at H_2 (because of the rapid motion of both H_2 and H_T^0) or even forcing exchanges $H_T^0 + H_2 \rightarrow H_2 + H_T^0$. This would not lead to stable tri-hydrogen complexes but would induce ortho-to-para transitions very efficiently. Estimating a rate for such interactions is tricky. The rate is proportional to the concentrations of o - H_2 and H_T^0 , the diffusivity of H_T^0 , and some capture radius. In the Raman studies, concentrations are of the order of 10^{19} cm^{-3} , 1000 higher than in the IR studies. The diffusivity of H_T^0 is unknown, but the estimated [22,23] 25 orders of magnitudes (!) above that of H_{BC} at low temperatures suggest that any number is possible.

Abstract

A Raman study of hydrogen stretching modes in vacancy-hydrogen defects (VH_n , $n = 1, 2, 3, 4$) is presented. The positions of the vibrational modes are compared to recent IR absorption results. The Raman lines exhibit pronounced polarization due to the $\langle 111 \rangle$ orientation of the silicon-hydrogen bond. Based on the defect symmetry derived from the polarization dependent Raman signals we assign the Raman lines measured at room temperature to the following defects: VH_4 : 2234 cm^{-1} (A_1 mode), 2205 cm^{-1} (T_2 mode); V_2H_6 : 2180 cm^{-1} (A_{1g} mode), 2155 cm^{-1} (E_g mode). We tentatively attribute the 2120- and 2099-cm^{-1} lines to VH_2 and the 2022-cm^{-1} line to VH . © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Vacancy; Raman scattering

1. Introduction

Hydrogen-related defects in silicon have been investigated extensively for the last two decades [1,2]. A model for the vacancy-hydrogen defects consisting of a single vacancy and up to four hydrogen atoms (VH_n with $n = 1, 2, 3, 4$) was developed, based on EPR, infrared absorption, and DLTS measurements, as well as on theoretical studies [3–14].

First Raman measurements on hydrogen-related defects in silicon were made on remote plasma hydrogenated samples [15]. A few Raman bands in the region $2000\text{--}2200\text{ cm}^{-1}$ were found and interpreted as hydrogen-related stretching modes of an extended defect called platelet. In this work we report on a Raman spectroscopy study of proton-implanted silicon. In our study, we are able to identify local vibrational modes

(LVMs) of different VH_n defects. Due to the selection rules, Raman spectroscopy gives a possibility to probe LVMs, which are not active in infrared absorption, and, which in combination with IR absorption and EPR studies allow us to better model the properties of the hydrogen-related defects in silicon.

2. Experimental

Silicon samples used in this study were n-type, phosphorus-doped, Cz (100)-wafers with resistivity of either 2 or $0.75\text{ }\Omega\text{ cm}$. Implantation doses varied from 1×10^{16} to $2.5 \times 10^{16}\text{ cm}^{-2}$. In order to study the thermal stability of the Raman lines a few samples were then annealed at 400°C in air. The annealing time varied from 2 min to 11 h.

The details of the Raman setup are described elsewhere [16]. Polarized Raman spectra were collected in a pseudobackscattering geometry. The polarization geometry is defined with respect to the sample surface (100): the x , y , and z axes are parallel to [100], [010], and [001], while y' and z' axes are parallel to [011], and

$[0\bar{1}1]$. In the notation $\{a[b,c]d\}$, $a(d)$ refers to the propagation vector of the incident (scattered) light, while $b(c)$ refers to the polarization vector of the incident (scattered) light.

3. Results and discussion

Fig. 1 shows typical room temperature Raman spectra measured on the hydrogen-implanted silicon: Label (a) refers to the as-implanted sample and (b) to the sample annealed at 400°C. The implantation gives rise to a number of Raman lines in the range of 1900–2250 cm^{-1} , which are characteristic of Si–H stretch LVMs. Indeed, in the deuterium-implanted sample, all these lines shift downwards in frequency by approximately a factor of $\sqrt{2}$, which proves that these are LVMs of hydrogen-related defects. The most prominent lines in the spectrum of the as-implanted sample are those at 1923, 1980, 2022, 2060, 2120, 2180, and 2234 cm^{-1} as well as a broad band centered at $\sim 2000 \text{ cm}^{-1}$. As can be seen from Fig. 1(b), annealing at 400°C removes the lines at 1923, 1980, 2022, and 2060 cm^{-1} from the spectrum and makes those at 2180 and 2234 cm^{-1} much stronger.

Careful investigation of the spectra shows that the lines at 2234, 2180, and 2120 have weak satellites located at 2205, 2155, and 2099 cm^{-1} , respectively (see the inset in Fig. 1). Relative intensities within each pair of these lines do not depend on the sample, implantation dose, as well as annealing temperature. Based on these findings we identify each pair of the lines as LVMs originating from the same defect.

Polarized Raman spectra measured on the sample annealed at 400°C and the as-implanted sample are presented in Figs. 2 and 3, respectively. As one can see, all Raman lines have maximum intensity in the $\{\bar{x}[z',z']x\}$ geometry, whereas in the $\{\bar{x}[z',y']x\}$ geometry they are very weak or nearly absent. This result may be

Fig. 1. Raman spectra measured at room temperature on the H_2^+ -implanted sample: (a) as-implanted sample and (b) after annealing at 400°C for 2 min. Spectra are offset vertically for clarity.

Fig. 2. Polarization Raman spectra measured at room temperature on the H_2^+ -implanted sample after annealing at 400°C for 2 min. Polarization geometry is defined with respect to the sample normal $[1\ 0\ 0]$. Spectra are offset vertically for clarity.

understood if we assume that the majority of the defects responsible for these Raman lines are vacancy-hydrogen complexes. Si–H bonds comprising these defects point almost in the $\langle 111 \rangle$ direction. Because LVMs spectroscopy probes the local trigonal symmetry of the Si–H bonds, this implies, according to the selection rules, maximal intensity in the $\{\bar{x}[z',z']x\}$ and zero intensity in the $\{\bar{x}[z',y']x\}$ geometry [17]. Let us now discuss the individual properties of the Raman lines.

3.1. 2205- and 2234- cm^{-1} lines

The two lines have the highest frequencies of all hydrogen-related Raman modes in our samples. The defect responsible for them is stable up to 400°C. At 10 K, the position of the 2205- cm^{-1} line (2223 cm^{-1}) coincides with that of the T_2 mode of VH_4 , whereas the frequency of the 2257- cm^{-1} line coincides with that

predicted for the infrared inactive A_1 mode of VH_4 [12]. It follows from the polarized spectra (see Fig. 2) that the intensity of the 2234-cm^{-1} line is maximum in the $\{\bar{x}[z', z']x\}$ and $\{\bar{x}[z, z]x\}$ geometries and equals zero in the $\{\bar{x}[z', y']x\}$ and $\{\bar{x}[z, y]x\}$ geometries, whereas intensity of the 2205-cm^{-1} line is maximum in the $\{\bar{x}[z', z']x\}$ and $\{\bar{x}[z, y]x\}$ geometries and equals zero in the $\{\bar{x}[z', y']x\}$ and $\{\bar{x}[z, z]x\}$ geometries. According to the selection rules for polarized Raman scattering, these properties are characteristic for the A_1 and T_2 modes of a cubic defect [17]. Based on this we assign the 2205- and 2234-cm^{-1} lines to the T_2 and A_1 modes of VH_4 .

3.2. 2155 and 2180-cm^{-1} lines

The defect responsible for the two lines is stable up to 400°C . At 10 K the 2155- and 2180-cm^{-1} lines shift upwards in frequency to 2165 and 2190 cm^{-1} , respectively, which is very close to the infrared absorption lines previously assigned to the E and A modes of V_2H_6 [18]. Polarization properties of the 2155- and 2180-cm^{-1} lines give support for the identification of the two lines as LVMs of V_2H_6 (see Fig. 2): Intensity of the 2180-cm^{-1} line is maximum in the $\{\bar{x}[z', z']x\}$ geometry and is reduced by more than 95% in the $\{\bar{x}[z', y']x\}$ geometry, whereas the 2155-cm^{-1} line is most intense in the $\{\bar{x}[z', z']x\}$ and $\{\bar{x}[z, y]x\}$ geometries and is much weaker in the $\{\bar{x}[z', y']x\}$ and $\{\bar{x}[z, z]x\}$ geometries. This is what is expected for the A and E modes of a trigonal defect.

The point group of V_2H_6 is D_{3d} , which implies that such a defect should possess four LVMs, labeled A_{1g} , E_g , A_{2u} , and E_u . The ungerade modes A_{2u} and E_u are active in infrared absorption, whereas the gerade modes A_{1g} and E_g are active in Raman scattering. The fact that the frequencies of the modes detected in Raman spectroscopy and infrared absorption are very close is consistent with our expectations. The repulsion between hydrogen atoms residing in the same vacancy is substantial and gives the dominant contribution to the $\sim 25\text{ cm}^{-1}$ splitting between the E and A modes (gerade and ungerade). However, the repulsion between two hydrogen atoms in two different vacancies will be much less due to the substantial large separation distance between the hydrogen atoms. The splitting between the gerade and the ungerade modes originates from the interaction between hydrogen atoms in different vacancies. Hence, a small splitting is expected in accordance with our observations.

3.3. 2099 and 2120-cm^{-1} lines

The defect responsible for the two lines is stable up to 400°C . At 10 K the 2099- and 2120-cm^{-1} lines shift upwards in frequency to 2121 and 2144 cm^{-1} , respectively, which coincide, within the accuracy of our setup, with the infrared absorption lines previously assigned to

the B_1 and A_1 modes of VH_2 [8,12]. Unfortunately, rather weak intensities of the two lines in our polarized Raman spectra did not allow to determine the symmetry of the defect. However, our data (see Fig. 2) do not contradict the C_{2v} (orthorhombic I) point group expected for VH_2 . Therefore, it would be quite tempting to identify the 2099- and 2120-cm^{-1} lines as LVMs of VH_2 . However, thermal stability of the defect is not in favor of this assignment: According to the FTIR absorption data [8,12], VH_2 decays at temperatures above 250°C , while the 2099- and 2120-cm^{-1} lines are present in the spectra after annealing at 400°C . Nevertheless, direct comparison with the FTIR data should be made with some care, because the doses employed in FTIR absorption studies were at least one order of magnitude less compared to ours, which may give a difference in thermal stability of the defect. Another explanation of the discrepancy in thermal stability of the 2099- and 2120-cm^{-1} lines and that of VH_2 could be that the defect responsible for these lines is VH_2 perturbed by VH_n ($n = 1, 2, 3$) [19]. Thus, both FTIR absorption and Raman scattering measurements made on the same sample are needed to investigate whether the two lines originate from VH_2 . Therefore, at this stage, we can only tentatively assign the 2099- and 2120-cm^{-1} lines to the LVMs of VH_2 .

3.4. 2022-cm^{-1} line

The defect responsible for this line decays at 400°C . Position of the 2022-cm^{-1} line in the spectra measured at 10 K (2038 cm^{-1}) coincides with the infrared absorption line tentatively assigned to a LVM of VH^0 [20]. Our polarization Raman measurements give support to this assignment (see Fig. 3): The 2022-cm^{-1} line is most intense in the $\{\bar{x}[z', z']x\}$ geometry and is reduced by more than 95% in the $\{\bar{x}[z', y']x\}$ geometry, which suggests the A mode of a trigonal defect.

4. Summary

Hydrogen-implanted silicon was studied by Raman scattering spectroscopy. From polarization of Raman lines in correlation with previous IR absorption studies and isotope substitution experiments the pairs of Raman lines at 2234 , 2205 and 2180 , 2155 cm^{-1} were assigned to the LVMs of VH_4 and V_2H_6 , respectively. We give a tentative assignment for the 2120- and 2099-cm^{-1} lines as LVMs of VH_2 and the 2022-cm^{-1} line as LVM of VH .

On the nature of hydrogen-related centers in p-type irradiated silicon

Abstract

Hydrogen interaction with the radiation defects is studied by the DLTS and MCTS techniques. Hydrogenation was carried out during wet chemical etching in acid solutions and following reverse bias annealing at 380 K. The levels $H4 = E_v + 0.28$ eV and $E4 = E_c - 0.31$ eV are formed as a result of the hydrogenation in all samples irradiated with electrons at room temperature. The levels are not found in irradiated samples which were annealed at 620–650 K before the hydrogenation. Another prominent level $H3 = E_v + 0.51$ eV is introduced by hydrogenation of as-irradiated float-zone silicon. Czochralski samples have to be annealed at 450 K before hydrogenation to form the H3 level. The H3 center is not formed in the samples annealed at ~ 650 K before hydrogenation. The nature of the hydrogen-related centers is discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Radiation defects

1. Introduction

In spite of many years of investigations, little is known about the complexes formed due to room-temperature hydrogenation of radiation-induced defects in silicon. In fact, only the VOH complex with the acceptor level at $E4 = E_c - 0.31$ eV has been studied in detail [1–3], including the tentative microscopic identification by the EPR technique [4]. Another prominent level $H4 = E_v + 0.28$ eV resulted from hydrogenation of irradiated Czochralski-grown silicon, has been ascribed to the COH complex based on a one-to-one correlation between the formation of this level and the C_iO_i complex passivation during reverse-bias annealing (RBA) at 380 K [5]. However, this assignment is not favored by the level structure of COH predicted by recent calculations [6]. Therefore, to gain further insight in the nature of the centers formed by hydrogenation of

irradiated silicon, we have studied silicon crystals with different content of the background impurities (O, C), paying special attention to the annealing kinetics of precursors of the hydrogen-related centers.

2. Experimental

Experiments were carried out on p-type silicon crystals grown by the Czochralski (Cz) and floating zone (FZ) method with boron concentrations $(0.6 \text{ to } 15) \times 10^{15} \text{ cm}^{-3}$. The samples were irradiated with 6 MeV electrons at room temperature. Hydrogen was incorporated into crystals during wet chemical etching (WCE) in acid solution ($\text{HF} : \text{HNO}_3 = 1 : 7$). The reverse-bias annealing (RBA) at 380 K was used to move hydrogen deeper into the crystals [7].

The semitransparent aluminum Schottky contacts were evaporated to allow standard DLTS and minority carrier transient spectroscopy (MCTS) measurements. However, the amplitudes of the MCTS peaks did not reflect the minority carrier trap concentration due to the front-side excitation.

3. Results and discussion

The effect of hydrogenation on the deep-level spectrum of irradiated p-type FZ silicon is demonstrated in Fig. 1. The DLTS peaks of the major radiation defects, C_sC_i , divacancy (V_2), and C_iO_i , decrease, while two novel peaks, H4 and H3 = $E_v + 0.51$ eV, arise in the hydrogenated region. It is seen in Fig. 1 and is confirmed by detailed depth profile measurements in FZ crystals that the concentration of the H4 centers can exceed the initial (before hydrogenation) concentration of the C_iO_i complexes. This result rules out C_iO_i as a precursor of the H4 level. In addition, the H3 level, which was not detected after a similar treatment in Cz-Si [5], is prominent in the FZ crystals.

To learn more about the precursors of the H4 and H3 centers, the irradiated samples were subjected to thermal annealing in the temperature range 400–650 K. Two examples of the DLTS and MCTS spectra measured on the annealed samples before and after hydrogenation are displayed in Fig. 2. Annealing at 570 K (Figs. 2a and b) produces significant changes in the deep-level spectrum. The peaks related to the C_sC_i complex (not shown) and divacancy disappear, while the center identified earlier as the B_iC_s pair [8] is formed in significant concentrations. Nevertheless, the H4 and H3 centers are still formed after hydrogenation. The signature of the VO center is seen in the MCTS spectrum, and the E4 level also appears after hydrogenation. Annealing at higher temperatures (Fig. 2c and d) destroys the VO complex too. Neither H4 nor E4 levels are detected in such samples after hydrogenation, while H3 remains to be the dominant feature in the hydrogenated region.

A similar picture is observed in Cz-Si. Pre-annealing of the VO centers prevents both E4 and H4 level

Fig. 1. DLTS spectra in p-type irradiated FZ-Si ($[B] = 2 \times 10^{15} \text{ cm}^{-3}$) before (dashed curve) and after (solid curve) hydrogenation. Rate window $e_p = 52 \text{ s}^{-1}$.

Fig. 2. MCTS (a,c) and DLTS (b,d) spectra measured in the FZ-Si pre-annealed at (a,b) 570 K and (c,d) 620 K before (dash curves) and after (solid curves) hydrogenation.

formation. The H3 level, which is not formed in as-irradiated Cz-Si, arises like in FZ-Si if the samples are annealed before the hydrogenation at ~ 450 K. The precursor of H3 is less stable in Cz-Si, and the H3 centers are not formed in Cz-Si after pre-annealing at ~ 600 K.

The H4 center is formed both in Cz and FZ irradiated crystals due to subsequent hydrogenation, as well as during proton implantation. On the other hand, the H4 concentration is very low after irradiation of pre-hydrogenated silicon. This indicates that the most probable mechanism of its formation is an addition of the hydrogen atom to a stable radiation defect. This precursor apparently does not contain shallow dopants, because H4 is created both in n- and p-type silicon in similar concentrations. The H4 center forms at higher concentrations than the V_2 , C_sC_i , and C_iO_i complexes. Only one electrically active stable radiation defect, VO, could be considered as the H4 precursor, which is consistent with the annealing data in Fig. 2. Taking into account that the H4 formation kinetics indicate that the center contains only one hydrogen atom [9], one can assume that H4 is a second level of the VOH complex. This assignment is supported by a similar annealing kinetics of the VOH and H4 levels [10]. Another

possibility, which should be discussed, is the formation of H4 by hydrogenation of an electrically inactive radiation-induced defect with the annealing temperature close to that of the VO centers.

The H3 center was reported in room-temperature proton implanted p-type silicon with different contents of background impurities (Cz, FZ, and epitaxial crystals) [11]. Our measurements show that the center can also be formed due to hydrogenation of the samples contained only stable radiation defects. We find that the H3 concentration is relatively high in the crystals with higher boron doping, but the centers are not detected in hydrogenated Al-doped samples, evidencing the boron-related nature of the H3 complex. This conclusion is supported by formation of the H3 precursor in irradiated Cz-Si after annealing at 450 K, which destroys the abundant B_iO_i complexes in Cz-Si. The boron-related precursor still escapes detection with electrical methods. However, the existence of a latent source of interstitial boron atoms in irradiated silicon is confirmed by the annealing-induced formation of the B_iC_i pairs in FZ-Si (Fig. 2), where the B_iO_i complexes are not detected.

4. Conclusion

Using the DLTS and MCTS technique, we have studied precursors of the prominent hydrogen-related $H4 = E_v + 0.28$ eV and $H3 = E_v + 0.51$ eV centers in irradiated p-type silicon. Comparison of the defect concentrations shows that among the stable electrically active complexes, only the VO center could be the precursor of the H4 level. This assumption is consistent with the annealing temperature of the H4 precursor. The

H3 center is a boron- and hydrogen-related complex with the precursor which anneals out at 600–650 K.

Abstract

The depth profiles of boron–hydrogen pairs formed in Si crystals by wet chemical etching (WCE) are calculated. The evolution of boron–hydrogen pair distribution after WCE is observed. The fits to the experimental profiles allow to estimate the hydrogen diffusivity at room temperature as $D_H = 2.4 \times 10^{-10} \text{ cm}^2/\text{s}$. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Diffusion; Shallow acceptor passivation

1. Introduction

Wet chemical etching (WCE) is used for hydrogen introduction into silicon to study the interaction of hydrogen with shallow and deep level defects [1–5]. The hydrogen diffusivity D_H at room temperature extracted from the WCE experiments [1,3] was found to be much higher than that extrapolated from the high-temperature (1000–1200°C) permeation study [6]. In these experiments, D_H was estimated under the assumption that the measured profiles of hydrogen-related defects were formed directly during WCE. Calculations of the boron–hydrogen profiles after WCE [7] showed that under this assumption a proper fit of measured profiles was possible for high hydrogen diffusivity ($D_H > 2 \times 10^{-9} \text{ cm}^2/\text{s}$). However, reasonable fits were also reported [7] for $D_H = 8 \times 10^{-11} \text{ cm}^2/\text{s}$ (the expected room temperature value from the literature [6]), with the additional assumption of a high enough free hydrogen concentration during WCE. The decay of the free hydrogen concentration after WCE leads to an apparent transient diffusion. Therefore, the problem of D_H evaluation from WCE experiments is closely associated with the question about the hydrogen concentration

near the surface during WCE and about the effect of hydrogen transient diffusion. To overcome this problem some additional information about the hydrogen concentration in the near-surface layer is necessary, which can be obtained from the evolution of the hydrogen–boron pair profile.

In the present work, the transient diffusion of hydrogen is experimentally detected in low doped p-Si crystals, and the hydrogen diffusivity at WCE temperature is estimated.

2. Experimental

The experiments were carried out on floating zone (FZ) grown p-type Si wafers doped with boron to a concentration of $4 \times 10^{13} \text{ cm}^{-3}$. To introduce hydrogen, the samples were etched in an acid mixture ($\text{HF}:\text{HNO}_3=1:7$), the etching rate was $2\text{--}4 \times 10^{-6} \text{ cm/s}$. The Schottky diodes of 3 mm in diameter were formed by thermal evaporation of Al on the freshly etched surface. The ohmic contacts were made by scratching an Al–Ga alloy onto the back surface of the samples. The profiles of the neutral hydrogen–boron pairs formed due to hydrogen–boron interaction were determined as a deficiency of electrically active boron concentration measured by the capacitance–voltage

E-mail address: yakimov@ipmt-hpm.ac.ru (E.B. Yakimov).

($C-V$) method. To observe the hydrogen transient diffusion, the time between WCE and measurements was decreased to be as small as possible. The minimum time necessary to prepare the Schottky barriers and ohmic contacts and to start the $C-V$ measurements was about 18 min.

3. Simulation of hydrogen penetration

The calculations of the distribution of hydrogen and hydrogen-related centers are carried out under the assumption that boron is the most efficient hydrogen trap. The electric field effect due to boron passivation is included in the calculations. The following system describing the hydrogen transport is solved numerically:

$$\frac{\partial H}{\partial t} = D_{H1} \frac{\partial^2 H}{\partial z^2} + \frac{eD_{H1}}{kT} \frac{\partial}{\partial z} \left(H \frac{\partial \varphi}{\partial z} \right) + V \frac{\partial H}{\partial z} - \frac{H}{\tau} \frac{N_B}{N_{B_0}},$$

$$e\varphi = kT \ln \left(\frac{N_B}{N_{B_0}} \right),$$

$$\frac{\partial N_B}{\partial t} = V \frac{\partial N_B}{\partial z} - \frac{H}{\tau} \frac{N_B}{N_{B_0}}, \quad (1)$$

with the boundary condition

$$F_0 = \left. \frac{\partial H}{\partial z} \right|_{z=0} = \text{const}, \quad (1a)$$

where H is the hydrogen concentration, z the depth from the etched surface, V the etching rate, φ the electrostatic potential determined by the non-uniform boron passivation, N_{B_0} and N_B the boron concentrations before and after WCE, respectively, $\tau = (4\pi D_{H1} r_B N_{B_0})^{-1}$, r_B the radius for hydrogen capture by boron atoms and F_0 the hydrogen flow through the surface. The term including V describes the effect of moving crystal surface during WCE. Hydrogen transport after etching is simulated by the same equations with $V = 0$ and $F_0 = 0$.

In accordance with Ref. [7], the simulation shows that the final hydrogen-related defect profiles formed during WCE and subsequent hydrogen transient diffusion are controlled both by D_{H1} and F_0 and it is practically impossible to obtain these values separately by fitting one experimental profile only. However, taking into account that the evolution of the profiles is determined by the amount of free hydrogen available after etching, a fit to several profiles measured at different times after WCE allows one to get a more reliable D_{H1} estimation. The simulations show a more pronounced relaxation of the hydrogen distribution with longer duration in low doped crystals. In accordance with this prediction, we measure the hydrogen transient diffusion after WCE on low doped p-type Si wafers.

Fig. 1. Carrier concentration profiles measured 18 (triangles) and 30 min (circles) after WCE. The corresponding profiles calculated with $D_{H1} = 2.4 \times 10^{-10} \text{ cm}^2/\text{s}$ are shown by solid lines.

4. Experimental results and discussion

The typical charge carrier concentration profiles in p-type Si measured 18 and 30 min after WCE are presented in Fig. 1. Boron is passivated near the surface, and in the bulk the charge carrier concentration approaches the initial boron concentration. A longer storage time after WCE leads to boron passivation at larger depth, and in 30–40 min after WCE the boron profile is found to reach its final form. The change of the charge carrier profile with the storage time indicates the existence of free hydrogen (or some unstable hydrogen-related complexes) in the near-surface layers after WCE. In the simulation, we assume that hydrogen does not out-diffuse and that the effect of the Schottky barrier on hydrogen transport can be neglected. The fits to the experimental profiles are also presented in Fig. 1. The profiles were calculated with $D_{H1} = 2.4 \times 10^{-10} \text{ cm}^2/\text{s}$, which correlates well with the value extrapolated from high-temperature diffusion studies [6]. A decrease of D_{H1} leads to an increased difference between the two simulated profiles and to an increase of time necessary to reach the stable position. On contrary, an increase of D_{H1} leads to a decrease of the difference between the profiles.

5. Conclusion

Hydrogen penetration into p-type Si under WCE and subsequent transient diffusion was measured and the profiles were analysed. It is found that the measured final hydrogen–boron pair profiles can be well fitted with D_{H1} varying in a wide range under the assumption of a rather high free hydrogen concentration during WCE. The measurement of profile evolution allows one to determine the diffusivity D_{H1} at room temperature.

Complexes of point defects and impurities in electron-irradiated CZ-Si doped with hydrogen

A. Nakanishi, N. Fukata, M. Suezawa*

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba, Sendai 980-8577, Japan

Abstract

We studied complexes generated by electron-irradiation of CZ-Si crystals pre-doped with hydrogen (H) from the measurements of optical absorption spectra. Specimens were prepared from a non-doped CZ-Si crystal. They were doped with H by heating at 1300°C in H₂ gas. They were then irradiated with 3-MeV electrons at room temperature. We measured their optical absorption spectra by an FT-IR spectrometer at about 7 K. An 836-cm⁻¹ peak which is due to a V–O pair was very strong. Optical absorption peaks due to complexes of H and self-interstitial (I) such as IH₂ (1987-cm⁻¹ peak), I₂H₂ (1870-cm⁻¹ peak) and I₃H₂ (1959-cm⁻¹ peak) were stronger than those of FZ-Si. Due to isochronal annealing, the intensity of V–O pair decreases at above 100°C. Simultaneously with this decrease, two new peaks appeared at about 2126 and 2151 cm⁻¹. This is due to a formation of VOH₂ complex by a reaction between a V–O pair and a H₂. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Oxygen; Hydrogen; Electron irradiation

1. Introduction

As shown in previous papers [1,2], we succeeded to detect vacancies (abbreviated as V hereafter), self-interstitials (I) and Frenkel-pairs (FP) generated by electron-irradiation of floating-zone grown Si (FZ-Si) crystals. They were detected not directly but indirectly: we detected them in the form of complexes of those point defects and hydrogen molecules (H₂) which were doped before irradiation. It is interesting to perform similar studies for the Czochralski-grown Si (CZ-Si) crystals since oxygen (O) concentration is very high in those crystals. We expect following two effects in the case of CZ-Si. First, it is expected that vacancies mainly form pairs with oxygen atoms and hence complexes of V and H₂ will not be formed since concentrations of O and H are around 1×10^{18} and 1×10^{16} cm⁻³, respectively. Second, the concentration of IH₂ is expected to be larger than that in FZ-Si since

recombination of V and I will be much reduced in CZ-Si compared with the case of FZ-Si if the formation of V–O pair occurs efficiently.

2. Experimental

Specimens were prepared from a high-purity (carrier density at RT was lower than about 4×10^{13} cm⁻³) CZ-Si crystal. Oxygen concentration determined from optical absorption at about 9 μm at RT with a conversion factor of 3.03×10^{17} atoms cm⁻² was 1.6×10^{18} cm⁻³. After cutting, mechanical shaping and chemical etching, specimens were doped with H by heating in H₂ gas at 1300°C for 1 h followed by quenching in water. Most hydrogen atoms are in a molecular state [3], H₂, and some form H₂O complexes [4]. They were then irradiated with 3-MeV electrons at RT. To determine thermal stability of defects, isochronal and isothermal annealing experiments were performed with the use of an oil-bath. Optical absorption spectra were measured with an FT-IR spectrometer at 7 K with a resolution of 0.25 cm⁻¹.

3. Results and discussion

Fig. 1 shows an optical absorption spectrum at around 1900 cm^{-1} . Defects responsible for the 1987-cm^{-1} and 1990-cm^{-1} peaks and 1870-cm^{-1} peak were proposed to be due to an IH_2 and I_2H_2 complexes, respectively [1,2], where an IH_2 denotes a complex of one I and two H atoms. The 1959-cm^{-1} peak was proposed to be due to I_3H_2 based on the dependence of its intensity on the electron dose [5].

Fig. 2 shows the dependences of peak intensities of those complexes on the electron dose of FZ-Si and CZ-Si. The data points were omitted for simplicity. As clearly seen, the concentrations of I-related complexes in CZ-Si are larger than those in FZ-Si. As described in Section 1, this is probably due to low probability of mutual annihilation of V and I because V's easily form pairs with oxygen atoms (V–O pairs). The peak intensity due to VH_2 in CZ-Si was much weaker than that of IH_2 , being smaller than $1/10$ at the irradiation dose of $4 \times 10^{17}\text{ cm}^{-2}$, whereas about $2/3$ in the case of FZ-Si. This is also due to high efficiency of V–O pair formation.

Fig. 3 shows the isochronal annealing behaviors of V–O pair (836-cm^{-1} peak) and newly appeared 2126-cm^{-1} peak. Annealing duration was 30 min at each temperature. Two new peaks at 2126.4 (abbreviated as 2126 hereafter) and 2151.5 (2152) cm^{-1} appeared due to annealing. The isochronal annealing behavior of the 2152-cm^{-1} peak was similar to that of the 2126-cm^{-1} peak, suggesting that the same defect is responsible for those peaks. Fig. 4 shows spectra of FZ-Si at as-irradiated state and that of CZ-Si annealed at 145°C . Two peaks which are almost of maximum intensity at as-irradiated state in FZ-Si were due to VH_2 complexes

Fig. 1. Optical absorption spectrum around 1900 cm^{-1} . The complexes responsible for peaks are shown.

Fig. 2. The dependences of peak intensities of IH_2 , I_2H_2 and I_3H_2 on electron dose in CZ-Si (solid lines) and in high-purity FZ-Si (dashed lines).

Fig. 3. Isochronal annealing curves of V–O pairs and the 2126-cm^{-1} peak. Annealing duration was 30 min at each temperature.

of different vibrational modes [6]. Similarity of two spectra and the isochronal annealing behaviors of V–O pair and the 2126-cm^{-1} peak below 200°C in Fig. 3 suggest that they are due to VOH_2 , supporting the model of Markevich et al. [7]. Markevich et al. found those peaks due to isochronal annealing of electron-irradiated n-type CZ-Si pre-doped with H and proposed that they are due to VOH_2 complexes based on theoretical calculations of vibrational frequencies of VOH_2 complexes.

Fig. 4. Comparison of optical absorption spectra of FZ-Si at as-irradiated state and CZ-Si after annealing at 145°C for 260 min. The electron doses of the former and the latter specimens were 1.6×10^{17} and $8 \times 10^{16} \text{ cm}^{-2}$, respectively.

To determine the activation energies of two stages of the decrease of V–O pair in Fig. 3, we performed isothermal annealing experiments. Fig. 5 shows the increase of the intensity of the 2126-cm^{-1} peak due to annealing at 100°C. The solid line is the fitting curve to determine the time constant. This curve was deduced under the assumption that the reaction was of the second order, namely, reaction occurred between two kinds of defects with similar concentrations. The fitting is good, which supports the assumption of second order reaction. The activation energy determined from the dependence of time constant on the isothermal annealing temperature was $0.86 \pm 0.04 \text{ eV}$, which is in good agreement with that ($0.78 \pm 0.05 \text{ eV}$) of H_2 diffusion [8]. Hence, this result and above isochronal annealing behaviors clearly show that an H_2 diffuses to a V–O pair and forms a VOH_2 complex.

The activation energy around 230°C in Fig. 3 was determined to be about $1.68 \pm 0.19 \text{ eV}$. As shown in Fig. 3, concentrations of V–O pairs and VOH_2 complexes decrease simultaneously. This suggests reaction between V–O pairs and VOH_2 complexes. According to literatures, the activation energy of V–O pair migration was reported to be 1.3 eV [9,10], 1.8 and 2.27 eV [11]. Our data is in the range of reported values. VOH_2 complexes are thought to be more difficult to do diffusion motion than V–O pairs since they are larger in size than V–O pairs. We therefore propose that the higher temperature stage in Fig. 3 corresponds to the diffusion of a V–O pair to a VOH_2 complex, resulting in the formation of a $(\text{VOH})_2$ complex.

Fig. 5. Isothermal annealing curve of the 2126-cm^{-1} peak due to annealing at 100°C.

4. Conclusion

We studied point defects in electron-irradiated CZ-Si pre-doped with hydrogen by means of optical absorption method. The concentrations of complexes of self-interstitials and hydrogen atoms in CZ-Si were larger than those in FZ-Si. Two new peaks at 2126 and 2152-cm^{-1} appeared due to annealing at around 150°C. They are due to VOH_2 complexes which are formed by a reaction between a moving H_2 and an immobile V–O pair. Both V–O pairs and VOH_2 complexes disappeared at around 250°C probably due to the formation of $(\text{VOH})_2$ complexes by a reaction between moving V–O pairs and immobile VOH_2 complexes.

Abstract

We studied the temperature dependences of line widths and peak positions of optical absorptions due to the hydrogen bound to point defects and acceptors in Si. Specimens were prepared from floating-zone-grown Si crystals of high-purity and of p-type, doped with group III acceptors. They were doped with H by heating at 1300°C in H₂ gas followed by quenching. The former specimen was then irradiated with 3 MeV electrons at RT to form complexes of H and point defects and the latter specimens were annealed at 150°C to form H–acceptor pairs. We measured their optical absorption spectra by an FT-IR spectrometer in the temperature range of 6 K and RT. Peaks due to localized vibrational modes of H bound to acceptors and point defects were well fitted with Lorentzian line shapes. The temperature dependences of those line widths and peak positions were analyzed with the dephasing model proposed by Persson and Ryberg. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Hydrogen; Silicon; Acceptor; Point defect; Line shape

1. Introduction

Hydrogen (H) in semiconductors is chemically active and easily forms pairs and complexes with other impurities and defects. Because of light mass, its vibrational frequencies of stretching modes are much higher than the bulk phonon frequencies. Moreover, the frequencies are sensitive to local atomic structure around H and are used to identify defects included in the complex (as a review article, see Refs. [1–3]).

One interesting feature of such localized vibrational modes is the temperature dependence of line widths and peak positions. The line width is known to be dominated by two dynamical processes, i.e., energy relaxation (relaxation time: T_1) and pure dephasing (T_2) [4]. Many studies have been done on the temperature dependences

of line widths and peak positions of H–dopant pairs in compound semiconductors [5]. There has been, however, no study on dephasing of H–impurity complexes and H–point defect complexes in Si.

2. Experimental

Specimens were prepared from various Si crystals grown by a floating-zone method (FZ-Si). After mechanical shaping and chemical polishing, they were doped with H by heating at 1300°C in H₂ gas followed by quenching in water. Hydrogen is in a state of H₂ molecule at RT [6]. A high-purity specimen was irradiated with 3-MeV electrons at RT to form H–point defect complexes. The total dose was $1.2 \times 10^{17} \text{ cm}^{-2}$. Specimens doped with group III acceptors with the concentrations of around $3 \times 10^{15} \text{ cm}^{-3}$ during crystal growth were annealed at 150°C to form H–acceptor pairs. Optical absorption spectra of these specimens

*Corresponding author. Tel.: +81-22-215-2040; fax: +81-22-215-2041.

E-mail address: suezawa@imr.edu (M. Suezawa).

were measured at various temperatures between 5 K and RT with an FT-IR spectrometer equipped with a continuous-flow-type liquid-helium cryostat. The resolution was 0.5 cm^{-1} in the case of H-acceptor pairs and 0.25 cm^{-1} in the case of H-point defect complexes.

3. Results, analysis and discussion

3.1. Atomic geometry

Prior to the description of experimental results, we describe the geometrical configurations studied in this paper. We roughly classify them into two groups. In the first group, H has one bond with one Si atom which is similar to H on the (111) surface, i.e., there are three Si atoms near the Si atom bonded to H, $[\text{Si}_3(\text{Si})\text{H}]$. The following complexes are thought to belong to this group; $\text{H}_2^*(\text{AB})$ (1838 cm^{-1} peak), $\text{VH}_2(1)$ and $\text{VH}_2(2)$ (2122 and 2145), V_2H_2 (2073), $\text{IH}_2(1)$ and $\text{IH}_2(2)$ (1987 and 1990) and I_2H_2 (1870), where $\text{H}_2^*(\text{AB})$ and VH_2 , for example, denote H at anti-bonding site in H_2^* and a complex of one V and two H atoms, respectively. Peak positions of optical absorption are shown in parentheses. In the second group, a H atom occupies the bond-centered site. Hence, H-acceptor pairs and $\text{H}_2^*(\text{BC})$ (2062) belong to this group, where BC denotes the bond-centered site. One characteristic feature of this group is that a H atom is squeezed between two large atoms, i.e., two Si atoms or Si atom and an acceptor atom.

3.2. Line width at very low temperature

At very low temperature, the line width of localized vibration is known to be dominated by energy relaxation process, i.e., the excited vibrational state is relaxed to the lowest vibrational state by emission of lattice phonons. Budde et al. [7] determined the vibrational lifetime (T_1) of bond-centered H in Si at very low temperatures by means of time-resolved, transient bleaching spectroscopy. The observed line width (Γ_0) at very low temperature was close to $1/2\pi cT_1$, where c represents the light velocity.

From the fittings of Lorentzians to the observed peaks cited in Section 3.1, we determined the peak positions and the line widths at half-maximum (FWHM: Γ) at various temperatures. Table 1 shows a summary of T_1 estimated from the line widths (Γ_0) at around 5 K. As can be clearly seen, T_1 of H-acceptor pairs and $\text{H}_2^*(\text{BC})$ are much shorter than those of H-point defect complexes. Hence, pairs of short relaxation time belong to the second group in Section 3.1. H atoms in those pairs occupy the bond-centered site and are squeezed much by the nearest two atoms (two Si or one Si and one acceptor) as described in Section 3.1. Hence, the coupling of the observed mode with surrounding lattice

Table 1

Relaxation time T_1 of H-acceptor pairs and H-point defect complexes in Si^a

Species	T_1 (ps)	Species	T_1 (ps)

Al-H	0.70	$\text{H}_2^*(\text{BC})$	1.8
Ga-H	1.2	I_2H_2	6.3
In-H	0.46	$\text{IH}_2(1)$	7.3
		$\text{IH}_2(2)$	7.2
		$\text{V}_2\text{H}_2(2)$	15
		$\text{VH}_2(1)$	17
		$\text{VH}_2(2)$	16

^aI and V indicate a self-interstitial and a vacancy, respectively. VH_2 , for example, denotes a complex of one V and two H atoms.

modes is thought to be large, which is the reason for short relaxation time.

3.3. Temperature-dependent line width

At high temperatures, the line width is thought to be dominated by dephasing processes, i.e., the vibrating excited system elastically collides with low-frequency phonon modes without emitting energy [4]. Since the thermal excitation of low-frequency phonons is required in the dephasing mechanism, this process is negligible at the low-temperature limit but becomes dominant as the temperature rises. Hence, we introduce the normalized line width $(\Gamma - \Gamma_0)/\Gamma_0$ to analyze the dephasing process.

Persson and Ryberg [8] proposed a dephasing model to explain the temperature dependences of the line width and peak position of vibrational mode of molecules adsorbed on a metal surface under the assumption that the local vibrational mode interacts with one phonon mode of low frequency. It is not possible to obtain analytical expressions of peak shift ($\Delta\omega$) and the change of FWHM ($\Delta\Gamma$) for the general case. The analytical expressions of these temperature dependences, however, are given as follows for the limiting case. We show, here, only the case of weak coupling limit.

$$\Delta\omega = \delta\omega/\beta, \quad (1)$$

$$\Delta\Gamma = (2\delta\omega^2/\eta)(\beta + 1), \quad (2)$$

where $\beta = \exp(\hbar\omega_0/2\pi kT) - 1$, $\delta\omega$ is the coupling constant of two modes, ω_0 is the vibrational frequency of coupling low-frequency mode with line width η and h , the Planck constant.

Figs. 1 and 2 show the dependences of the normalized line widths, $(\Gamma - \Gamma_0)/\Gamma_0$, of H-acceptor pairs and complexes of H and point defects on temperature. Figs. 3 and 4 show the dependences of peak positions of those defects on temperature. Solid lines are fitting curves due to the dephasing model proposed by Persson and Ryberg [8]. In the above fittings, we used analytical

Fig. 1. Dependences of the line widths of optical absorption peaks due to H-acceptors on temperature. Solid lines are fitting curves due to Eq. (2).

Fig. 2. Dependences of the line widths of optical absorption peaks due to complexes of H and point defects on temperature. Solid lines are fitting curves due to Eq. (2).

Fig. 3. Dependences of the peak shifts of optical absorption peaks due to H-acceptors on temperature. Solid lines are fitting curves due to Eq. (1).

Fig. 4. Dependences of the peak shifts of optical absorption peaks due to complexes of H and point defects on temperature. Solid lines are fitting curves due to Eq. (1).

expressions, i.e., Eqs. (1) and (2), at the weak coupling limit: the line width of low-frequency mode is larger than the coupling constant.

In Figs. 1–4, the fittings themselves seem to be good. In the case of H–point defect complexes and $H_2^*(AB)$, the vibrational frequency (ω_0) of low-frequency mode determined from the fitting of line width agreed well to that determined from peak position and the condition of weak coupling limit was also satisfied. On the other hand, the vibrational frequency of low-frequency mode determined from the line width did not agree with that determined from the peak shift in the case of H–acceptor pairs, $H_2^*(BC)$ and IH_2 . Hence, Persson and Ryberg's model at the weak coupling limit is applicable to the former and not applicable to the latter.

4. Summary

We studied the temperature dependences of line widths and peak positions of optical absorption peaks due to H–acceptor pairs, H–point defect complexes and H_2^* in Si. We analyzed them with the dephasing model at the weak coupling limit proposed by Persson and Ryberg. This model explained well the behaviors of H–point defect complexes (except IH_2) and $H_2^*(AB)$ but not those of H–acceptor pairs, $H_2^*(BC)$ and IH_2 .

Abstract

We studied point defects generated by electron-irradiation of hydrogenated Si crystals at low temperatures from the measurement of optical absorption due to hydrogen bound to point defects. Specimens of high-purity, n- and p-type floating-zone grown Si crystals were doped with H by heating in H₂ gas at 1300 °C followed by quenching. Then, they were irradiated with 6 MeV electrons at 270, 200 and 130 K. We measured their optical absorption spectra at 7 K with the use of an FT-IR spectrometer. The relative mobilities of various point defects were discussed from the relative intensities of 1838, 1987 and 2122 cm⁻¹ peaks which are due to H₂[•], IH₂ and VH₂, respectively, where V, I and H₂[•] denote a vacancy, a self-interstitial and H₂ in metastable state formed by a reaction between an H₂ and a Frenkel pair, respectively. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Electron irradiation; Vacancy; Self-interstitial; Frenkel pair

1. Introduction

As shown in previous papers [1,2], we have succeeded in detecting self-interstitials (abbreviated as I hereafter) and Frenkel pairs (FP) as well as vacancies (V) from the measurements of optical absorption of hydrogenated silicon crystals after electron-irradiation at RT. They are detected not directly but indirectly, i.e., via the complexes of those point defects and hydrogen molecules (H₂). The formation of these complexes were interpreted to be due their diffusion to H₂, which is effectively immobile [3] at around RT. According to this interpretation, it seems possible to measure the relative diffusion rates of these point defects from the measurement of optical absorption intensities which are proportional to their concentrations. To obtain some bits of information on the mobilities of V, I and FP, we performed electron-irradiation of hydrogenated Si at

various temperatures and measured their optical absorption spectra.

2. Experimental

Specimens were prepared from floating-zone grown Si (FZ-Si) crystals of n-type (phosphorus concentration: $1.5 \times 10^{16} \text{ cm}^{-3}$), high-purity (p-type carrier concentration at RT was $4.5 \times 10^{12} \text{ cm}^{-3}$) and p-type (boron concentration: $1.5 \times 10^{16} \text{ cm}^{-3}$). After cutting out specimens from above crystals, they were mechanically shaped and chemically etched to the size of $4 \times 6 \times 11 \text{ mm}^3$. To dope hydrogen, they were sealed in quartz capsules together with H₂ gas and heated at 1300 °C for 50 min followed by quenching in water. Hydrogen in Si at RT is in a state of H₂ [4]. They were then irradiated at 270, 200 and 130 K with 6 MeV electrons using a linear accelerator with an irradiation dose of $5 \times 10^{16} \text{ cm}^{-2}$. Specimens were placed in a cooled nitrogen-gas flow during irradiation. The specimen temperature was monitored with a

E-mail address: suezawa@imr.edu (M. Suezawa).

thermocouple. We measured their optical absorption spectra with an FT-IR spectrometer installed with a continuous-flow-type liquid He cryostat. Measurement temperature was about 7 K and the resolution was 0.25 cm^{-1} .

3. Results and discussion

Prior to showing the experimental results, we should consider the formation process of various complexes of point defects and H_2 . Due to electron-irradiation of specimens, FPs are first formed. Some of them diffuse to H_2 and form complexes, H_2^* , and some dissociate into V and I. We assume the dissociation rate is temperature-independent. Since the migration energies of V and I are small [5], they diffuse to various sinks and traps during irradiation. There are many paths to form complexes. Some form complexes with H_2 such as VH_2 , V_2H_2 , IH_2 and I_2H_2 , where an IH_2 , for example, is a complex of one self-interstitial and two H atoms. Some form complexes by themselves, for example, V_2 . Hence, it is not easy to obtain accurate information about the mobilities of V, I and FP from the measurement of the concentrations of complexes. We should fully analyze the formation processes of all complexes to determine the mobilities of above point defects. In the following, however, we simply assume that the relative intensities of IH_2 , VH_2 and H_2^* correspond to relative mobilities of I, V and FP, respectively. Hence, the deduced results may be insufficient in accuracy.

Fig. 1 shows optical absorption spectra of high-purity Si crystals irradiated at 270 K (upper spectrum) and 130 K (lower one). As seen, the absorption due to IH_2 at 1987 and 1990 cm^{-1} was the strongest after the irradiation at 270 K. On the other hand, after irradiation at 130 K, it was much weaker than that irradiated at 270 K and those of VH_2 and H_2^* were similar to those irradiated at 270 K. These results clearly show two features that the mobility of I has larger temperature dependence than those of V and FP and the mobilities of V and FP are larger than that of I at 130 K. Fig. 1 is thought to support above assumption that the dissociation rate of FP is temperature-independent since the intensities of VH_2 and H_2^* are similar after irradiation at 270 and 130 K.

Fig. 2 shows optical absorption spectra of n-type Si crystals irradiated at 270 K (upper spectrum) and 130 K (lower one). As seen, the absorption due to IH_2 was the strongest after 270 K irradiation, similar to Fig. 1. On the other hand, after irradiation at 130 K, it decreased much and those of VH_2 and H_2^* became larger than those irradiated at 270 K. These results show that the mobility of I has different temperature dependence from those of V and FP. The intensity of VH_2 was weak after 270 K irradiation. This is due to preferential formation

Fig. 1. Optical absorption spectra of high-purity specimens irradiated at 270 K (upper curve) and 130 K (lower curve). Complexes responsible for peaks were determined in previous studies [1,2].

Fig. 2. Optical absorption spectra of n-type specimens irradiated at 270 K (upper curve) and 130 K (lower curve).

of V-P pair as shown in the previous study [2]. The intensity of VH_2 in Fig. 2 after 6 MeV electron-irradiation at 270 K is about a 2.5 factor larger than that after 3 MeV electron-irradiation at RT. Hence, there may be an effect of irradiation energy on the formation of V-P pair.

Fig. 3 shows optical absorption spectra of p-type Si crystals irradiated at 270 K (upper spectrum) and 130 K (lower one). As seen, the absorption due to VH_2 was the strongest after 270 K irradiation. On the other hand,

Fig. 3. Optical absorption spectra of p-type specimens irradiated at 270 K (upper curve) and 130 K (lower curve). BH denotes a pair of a boron atom and an H.

after irradiation at 130 K, the intensity of H_2^+ became the largest, much larger than that at 270 K irradiation. The intensity of VH_2 after 130 K irradiation was similar to that after 270 K irradiation. These results show that the mobility of FP has a different temperature dependence from that of V. The intensity of IH_2 was weak after 270 K irradiation. This is due to replacement of occupation sites between an I and a substitutional B [5]: $\text{I} + \text{B}(\text{s}) \rightarrow \text{B}(\text{i}) + \text{Si}(\text{s})$, where (i) and (s) denote the interstitial and substitutional sites, respectively. The intensity of IH_2 in Fig. 3 after 270 K irradiation is about factor 3.4 times larger than that after 3 MeV irradiation at RT. Hence, there may be an effect from irradiation energy on the replacement. According to Fig. 3, the probability for the replacement of occupation sites seems to decrease due to irradiation at 130 K.

Properties of irradiation-induced vacancies in Si have been extensively studied and clarified well [5]. Hence, we estimate the relative intensities, IH_2/VH_2 and H_2^+/VH_2 , to determine the relative migration energies of I and FP to that of V. Such a procedure is necessary to correct possible change of irradiation conditions, such as the focusing of the electron-beam, depending on the irradiation temperature. Fig. 4 shows the dependence of relative intensities on the temperature in high-purity specimens. From the slope, we obtained energies of 7.4 and 21 MeV for H_2^+ and IH_2 , respectively. These energies are thought to be the differences of migration energies of FP and V and of I and V, i.e., their migration energies are the sum of above values and the migration energy of vacancy. Hence, these results show that the migration energies of V, I and FP are similar during electron-irradiation. Within our knowledge, no one has shown the diffusion of FP. The migration of FP suggests long lifetime of FP, i.e., the annihilation of FP is not easy and

Fig. 4. The dependences of the relative intensities of IH_2/VH_2 (circles) and H_2^+/VH_2 (triangles) in high-purity specimens on the irradiation temperature.

there may be energy barrier for recombination of V and I.

It is well known that an I in p-type Si crystals diffuses athermally even at 4.2 K. This athermal motion is explained by the Bougoïn-Cobett mechanism [6]. According to this model, the position where an I in one charge state is at a potential minimum corresponds to a potential maximum for an I in another charge state. Thus, an I will move toward its new minimum-potential position each time its charge state changes. According to our experiment, however, there is a migration energy of I even in p-type Si crystals. The lifetime of the charge state at the maximum potential of I for athermal diffusion may be shorter than the time for one atomic jump for diffusion motion, probably because of thermal excitation of the charge at high temperatures.

4. Conclusion

We studied the effect of irradiation temperature on the formation of complexes of point defects and H_2 in hydrogenated Si crystals. Relative intensities of optical absorption peaks due to complexes of point defects and H_2 strongly depended on the irradiation temperature. We interpreted these results under a simplified assumption that the relative intensities correspond to the relative mobilities of relevant point defects. According to above assumption, we determined the migration energies of an I and a FP relative to that of V during electron-irradiation.

Observation of two coupled defect levels on the hydrogen-passivated Si (100) surface

A.J. Reddy*, J. Michel, L.C. Kimerling

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Room 13-4110, 77 Massachusetts Ave, Cambridge MA 02139, USA

Abstract

We present the first electronic characterization of intrinsic defects on the hydrogen-passivated silicon surface. Surface recombination velocities, measured with radio-frequency photoconductance decay, show that lifetimes of both n- and p-type wafers change significantly with small changes in the background carrier concentration ($\eta \equiv \Delta n/p_0 \approx 0.05$). These effects are not explained by the Shockley-Read-Hall model for single-level defect recombination but can be understood by modeling the defect as a coupled, two-level (three charge state) system. By analogy with the P_b -center, these defects may be thought of as dangling bonds populated with zero, one, or two electrons. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Dangling bond; Minority carrier lifetime; Passivation; Surface defect

1. Introduction

Hydrogen passivation of the silicon surface is widely used to retard native oxide growth. Scanning tunneling microscopy (STM) studies of hydrogen-passivated silicon surfaces [1,2] show that dangling bonds arise at the ends of dimerized rows of the 2×1 surface reconstruction. Others have also shown that dangling bonds are formed when O_2 molecules dissolved in solution abstract hydrogen radicals from Si-H surface bonds [3].

We have previously used surface sensitive minority carrier lifetime measurements to study native oxide growth [4], metal deposition [5], and surface passivation [6]. We have further proposed the use of minority carrier lifetime as an in situ monitor for metal contamination in hydrofluoric (HF) acid baths [7]. More precise use of this technique requires a detailed understanding of the electronic nature of intrinsic surface defects.

2. Lifetime measurements

Lifetime measurements have been made using radio-frequency photoconductance decay (RF-PCD) [8]. Fig. 1 shows RF-PCD measurements for both n-type and p-type silicon samples immersed in 100:1 (0.5 wt%) HF solutions. The sample preparation procedure is described elsewhere [8]. A quartz halogen lamp with a maximum illumination of 1.5×10^{16} photons/(cm² s) has been used to change the background carrier concentration up to 5% for p-type wafers and 10% for n-type.

The Shockley-Read-Hall lifetime [9,10] for a single-level defect is given by

$$\tau_{SRH} = \frac{\tau_{LL} + \eta\tau_{HL}}{1 + \eta},$$

where τ_{LL} and τ_{HL} are the asymptotic low-level and high-level injection lifetimes, respectively, and η is the relative injection level ($= \Delta n/p_0$). This theory alone could explain the observed lifetime increase for the n-type data, if $\tau_{HL} \gg \tau_{LL}$, but is not consistent with the decrease in τ of over 50% for $\eta \approx 0.05$ observed for the p-type wafer.

Fig. 1. Minority carrier lifetime data, taken with RF-PCD, for n- and p-type silicon wafers immersed in solutions of dilute HF (0.5 wt%).

There are many known models for non-exponential decays: surface diffusion transients, trapping sites, and surface band-bending. Attempts have been made to apply each of these to our data, but all have flaws. Surface transients apply only to lifetimes below the transit time ($\approx 16 \mu\text{s}$ for p-type Si). Trapping sites need to be present in a very large concentration and should slow the initial carrier decay rate for biased data, but no such decrease is observed. A band-bending explanation would require that excess electrons somehow generate a surface potential that is further attractive to electrons. Failure of these models has led to the development of the two-level defect model.

3. The two-level defect model

A two-level defect has three charge states, D^+ , D^0 , and D^- , as shown in Fig. 2. The two mid-gap states of the defect correspond to transitions between these states. The two levels are coupled, as the second level can be occupied only when the first is already filled. At equilibrium, the change in the Gibbs free energy must be zero for adding an electron to either level. The enthalpy change for populating each of these levels is simply the defect energy level minus the Fermi energy: $\Delta H_1 = E_{T1} - E_F$ and $\Delta H_2 = E_{T2} - E_F$. The total entropy for a two-level defect is defined by the number of microstates that correspond to a given macrostate, i.e., defect level occupations f_1 and f_2 . A microstate for coupled levels requires partitioning the N_D defects into (1) $(1 - f_1) \times N_D$ D^+ states, (2) $(f_1 - f_2) \times N_D$ D^0 states, and (3) $f_2 \times N_D$ D^- states. The total number of microstates is then:

$$\Omega = \frac{N_T!}{(1 - f_1)N_T!(f_1 - f_2)N_T!f_2N_T!}; \quad S_{\text{tot}} = k_B \ln \Omega.$$

Fig. 2. Carrier-defect interactions in the two-level defect model. Each transition between states can occur either through capture of one carrier or emission of the opposite type of carrier.

The change in entropy involved in adding one electron to each defect level is then

$$\Delta S_1 = \Delta f_1 \times \left. \frac{\partial S_{\text{tot}}}{\partial f_1} \right|_{f_2} = k_B \ln \left(\frac{1 - f_1}{f_1 - f_2} \right),$$

$$\Delta S_2 = \Delta f_2 \times \left. \frac{\partial S_{\text{tot}}}{\partial f_2} \right|_{f_1} = k_B \ln \left(\frac{f_1 - f_2}{f_2} \right).$$

At equilibrium, $\Delta H = T\Delta S$, and the equilibrium defect occupations are determined to be

$$f_1 = \frac{1 + \beta}{1 + \beta + \alpha\beta}, \quad f_2 = \frac{1}{1 + \beta + \alpha\beta},$$

where $\alpha = \exp((E_{T1} - E_F)/k_B T)$ and $\beta = \exp((E_{T2} - E_F)/k_B T)$. From these equations, it is evident that $f_1 > f_2$ even when $E_{T1} > E_{T2}$, and there is no need to impose constraints that guarantee a physically meaningful value for $[D^0] = (f_1 - f_2)N_D$.

Assumptions about recombination kinetics are the same as the SRH model:

- capture is a first-order reaction between a defect site and a carrier,
- emission rates vary exponentially with the energy required, and
- defects are in quasi-equilibrium with both bands.

Fig. 3. Calculated recombination lifetimes for a typical single-level defect and for a two-level system that approximates the behavior of intrinsic defects on n- and p-type hydrogen-passivated Si (100) surface.

The four emission coefficients may be written in terms of capture coefficients and equilibrium defect occupations. The lifetime then varies with injection level as [11]

$$\tau(\Delta n) \equiv -\frac{\Delta n}{dn/dt} = \tau_0 \left(\frac{1 + \tau_{n1}\Delta n + \tau_{n2}\Delta n^2}{(1 + \tau_d\Delta n)(1 + \Delta n/(p_0 + n_0))} \right),$$

where τ_0 , τ_{n1} , τ_{n2} , and τ_d all can be written as functions of the four capture coefficients, the two energy levels, and the total concentration of defects.

Fig. 3 illustrates how the injection level dependence of a two-level defect can be much more complicated than the familiar SRH behavior of a single level. Defect levels for the two-level system have been chosen to roughly mimic the behavior we have observed for H-passivated silicon (100) surfaces. The parameter values are: $\sigma_c^1 = 10^{-16} \text{ cm}^2$, $\sigma_c^2 = 10^{-15} \text{ cm}^2$, $\sigma_h^1 = 10^{-16} \text{ cm}^2$, $\sigma_h^2 = 2 \times 10^{-15} \text{ cm}^2$, $E_{T1} = E_V + 0.95 \text{ eV}$, $E_{T2} = E_V + 0.63 \text{ eV}$. Different values for N_T have been used: $4 \times 10^{10} \text{ cm}^{-2}$ for p-type and 10^9 cm^{-2} for n-type. The doping level for all wafers was fixed at $2 \times 10^{15} \text{ cm}^{-3}$.

While the SRH lifetime changes only near the doping level, the two-level defect shows a much stronger dependence on Δn . The rapid lifetime drop observed for the p-type wafer is due to the speed of the D^0/D^- transition. At equilibrium, most defects are in the D^+ state, so this fast pathway is inaccessible. As the injection level increases, $[D^0]$ also increases and rapid recombination becomes possible. The lifetime continues to drop until the recombination rate is determined entirely by this D^0/D^- transition. For the n-type wafer near equilibrium, most defect sites are occupied and the fast D^0/D^- transition causes the lifetime to be low. The addition of excess carriers, combined with the high rate of electron emission from the shallow level E_{T1} , serves to decrease $[D^0]$ for moderate injection levels. The lifetime

Fig. 4. Possible physical states corresponding to the three electronic states of the surface defect. Each may play important roles in common silicon surface reactions.

thus rises in the intermediate regime (near the wafer doping level), before dropping off in the intrinsic (high-level injection) regime.

4. Physical significance

The precise nature of the defects on the H-passivated surface are not known. In analogy with P_b -centers observed at the Si-SiO₂ interface, it is likely that these defects are dangling bonds. Fig. 4 represents the three physical states for this defect. As was stated in establishing the model, the unoccupied defect state would have a net charge of $+q$. Simply on electrostatic grounds, this site should be very attractive for dissociated F^- ions in solution. The doubly occupied state will serve similarly as a source for electrons. In the process of native oxidation, electrons are transferred from the silicon surface to an adsorbed O₂ molecule. The density of doubly occupied sites may therefore be the limiting species in the degradation of the Si-H passivation. Metal contamination of silicon wafers also occurs by electron transfer from the surface. The doubly occupied dangling bond may prove to be a rate-limiting factor in the rate of metal deposition.

5. Conclusions

A model had been developed for carrier recombination in a two-level defect system. Equilibrium defect occupations are not determined by the Fermi level alone and a more complete approach, based on the total defect entropy, is required. The recombination kinetics are also more complicated and can produce rapid changes in the lifetime even for injection levels well below the doping level. Experimental measurements suggest that silicon (100) wafers immersed in dilute HF solutions are an example of a two-level defect system. The lifetime changes observed on p- and n-type wafers are both explained by a rapid D^0/D^- transition and a slow D^-/D^0 transition. The three defect species identified by this model are likely states of a dangling bond and may play important roles in charge transfer at the silicon surface.

Abstract

A new approach to generate stimulated emission in the terahertz (THz) range of the electromagnetic spectrum is presented. At low temperatures, population inversion between excited states of shallow impurity centers in silicon can occur due to peculiarities of electron–phonon interaction. The terahertz stimulated emission from impurity transitions was observed from bulk monocrystalline silicon doped by group V elements (P, Bi), excited by CO₂ laser radiation. © 2001 Elsevier Science B.V. 1. Introduction

At present, semiconductor lasers which are based on intracenter transitions of optically excited highly non-equilibrium charge carriers are intensively studied. Silicon is one of the most promising materials for such lasers. Erbium-doped silicon [1,2] can operate at a wavelength of around 1.55 μm on intracenter 4f-shell optical transitions of Er atoms. Recently, it has been demonstrated that optically excited hydrogen-like impurity centers in silicon are an efficient source for far-infrared stimulated emission [3–7]. In the case of hydrogen-like centers, the strong influence of electron–phonon interaction on the charge carrier distribution tends to form an equilibrium distribution of charge carriers. However, the specific nature of the phonon-assisted relaxation at low temperatures allows to obtain population inversion due to the suppression of acoustical phonon emission [5] or resonant interaction with

optical phonons [7] for particular excited impurity states.

Non-equilibrium free charge carriers in silicon are created by optical excitation of shallow impurity centers with CO₂ laser radiation. The carriers, optically excited from the ground state into the conduction band, lose their energy by emitting acoustical or optical phonons. The following intracenter relaxation of free charge carriers is a fast cascade process [8]. In n-type Si doped by shallow donor centers, the 2p₀ excited state is comparatively far spaced from the lower s-type states. Relaxation from the 2p₀ state by an acoustical phonon is suppressed, because the wave vector for relaxation by acoustical phonons through the relatively large energy gap is beyond the localization of the impurity states.

As a result, for most of n-Si media, e.g. for silicon doped by phosphor (Si:P), the 2p₀ state is relatively long living (ca. 15 ns [5]). The lower 1s(E,T) states have lifetimes of the order of 0.1 ns [5]. The accumulation of photoexcited carriers in the 2p₀ state in Si:P enables a population inversion between the 2p₀ and 1s(E,T) excited states [4]. This can be used to form a 4-level laser scheme with the 2p₀ state as the long-living upper

level (Fig. 1). Lasing from the 2p₀→1s(E) transition in optically pumped Si:P was reported in [5,6]. For silicon doped by bismuth (Si:Bi), the 2p₀ excited state has a very short lifetime (ca. 1 ps) because of resonant interaction with an optical phonon [9]. This results in a relatively small population of the split 1s(E, T) states, since the excited electrons relax from the 2p₀ state directly to the 1s(A) ground state. This can be used to form a 4-level laser scheme with less populated lower levels, the 1s(E, T) states (Fig. 2). Lasing from the 2p_±→1s(E) transitions in optically pumped Si:Bi is reported in [7].

2. Sample preparation

Low compensated (<1%) Si:P samples were grown by Czochralski (Cz) and float zone procedure with simultaneous incorporation of phosphor from the melt. The size of the samples is 7×7×5 mm³. The dominant phosphor concentrations in these samples are in the range (0.08–9)×10¹⁵ cm⁻³. A set of Si samples with phosphor concentration $N_P \approx 3 \times 10^{15}$ cm⁻³ and a boron compensation in the range 0.2–35% was prepared from

Fig. 2. float zone grown p-Si:B by neutron (³⁰Si(n, γ)→³¹Si(β⁻/2.6 h)→³¹P). Si:Bi samples with donor concentrations (0.05–2)×10¹⁵ cm⁻³ were grown using the float zone technique. Samples with different doping concentrations were cut in the form of rectangular parallelepipeds (7×7×5 mm³) from the Si crystal and then polished to provide a high-Q resonator. The crystals with low doping concentration (ca. 5×10¹³ cm⁻³) were used to identify the dominant dopant as well as the concentration of the incorporated electrically active centers by means of the Fourier transform absorption spectroscopy.

3. Experimental setup

The samples were mounted in a holder which was immersed in a liquid helium (LHe) vessel (Fig. 3). A grating tunable TEA CO₂ laser with a peak output power up to 2.5 MW in the wavelength range 9.2–10.7 μm was used as the pump source. The losses of the

Fig. 3. The experimental setup for observation of the emission from Si: (1) pump laser attenuator; (2) photon drag monitor; (3) pump beam; (4) far-infrared laser beam; (5) Si sample; (6) far-infrared filters; (7) far-infrared detectors; and (8) detector for pump beam alignment.

incident pump power were estimated to be about 7 dB. The FIR emission from the optically pumped Si samples was registered by a LHe cooled Ge:Ga photodetector, mounted in the same holder. For measurements of the emission spectra, the FIR radiation from the Si sample was guided out of the vessel by a stainless steel light pipe into a Fourier transform spectrometer or a grating spectrometer. An external Ge:Ga detector was used to detect the signal.

4. Results

All Si:P samples doped higher than $5 \times 10^{14} \text{ cm}^{-3}$ showed spontaneous emission when pumped by a CO_2 laser. The spontaneous emission increases with increasing doping concentration. For these samples, stimulated emission was observed for doping concentration in the range $N_P = (0.8\text{--}3) \times 10^{15} \text{ cm}^{-3}$. The neutron transmutation doped samples, which are heavily compensated, have a reduced laser threshold. The CO_2 laser pump intensity, necessary to exceed the Si:P laser threshold, was about 30 kW cm^{-2} at the pump wavelength $10.6 \mu\text{m}$ (Fig. 4a). The terahertz emission pulse from the Si:P laser started together with the pump pulse and had a duration of 70–100 ns, comparable with the full-width of half-maximum of the pump laser pulse (Fig. 5a). The spectrum of the stimulated emission from the Si:P sample was measured by a grating spectrometer with a resolution of 0.2 cm^{-1} (Fig. 6). A line at $54.1 \mu\text{m}$ was recorded, which corresponds to the $2p_0 \rightarrow 1s(\text{T})$ intracenter P transition.

Fig. 4. The dependency of far-infrared emission from the Si:P (a) and the Si:Bi (b) on the incident peak power from a CO_2 laser at $10.6 \mu\text{m}$. The readings of the CO_2 laser power are from the photon drag monitor: (a) triangles are for spontaneous emission from the Si:P samples with a phosphor concentration $N_P = 9 \times 10^{15} \text{ cm}^{-3}$ and squares are for stimulated emission from the Si:P samples with a phosphor concentration $N_P = 3 \times 10^{15} \text{ cm}^{-3}$ and (b) triangles are for spontaneous emission from the Si:Bi sample as cut with a bismuth concentration $N_{\text{Bi}} = 2 \times 10^{15} \text{ cm}^{-3}$ and squares are for stimulated emission from the same sample after polishing in order to get a high- Q resonator.

Stimulated emission was observed from the Si:Bi sample with a doping concentration of $2 \times 10^{15} \text{ cm}^{-3}$ after the sample was polished in order to provide a high- Q resonator (Fig. 4b). The CO_2 laser pump intensity, necessary to exceed the Si:Bi laser threshold, was about 500 kW cm^{-2} at the pump wavelength $10.6 \mu\text{m}$ (Fig. 4b). A delay of the stimulated emission pulse (50–200 ns) with respect to the pump pulse was observed and the duration of the laser pulse was not shorter than that of the pump pulse (about $1 \mu\text{s}$) (Fig. 5b). The spectrum of the stimulated emission from the Si:Bi sample was measured by a FTS with a resolution of 0.4 cm^{-1} (Fig. 7). A line at 191.6 cm^{-1} ($52.2 \mu\text{m}$) was recorded. This corresponds to the $2p_{\pm} \rightarrow 1s(\text{E})$ intracenter Bi transition.

Fig. 5. Traces of pump pulses (up) from the CO₂ laser and terahertz emission pulses from the Si:P (a) and the Si:Bi (b), when pumped by radiation at 10.6 μm.

Fig. 6. The stimulated emission spectrum from the Si:P sample recorded by a grating spectrometer.

5. Summary

The experiments yield an optimum doping concentration for the Si:P laser of $N_D - N_A = (3-4) \times 10^{15} \text{ cm}^{-3}$ with a compensation $N_A/N_D \geq 0.3$. Similar values are expected for the Si:Bi laser. Compensation of the samples reduces the concentration of D^- centers. This reduces the internal optical losses due to absorption of

Fig. 7. The stimulated emission spectrum from the Si:Bi sample recorded by a Fourier transform spectrometer.

the FIR laser emission by the D^- centers and, as a result, the laser threshold. The measured emission spectra reveal that the transitions taking part in the laser schemes are $2p_0 \rightarrow 1s(T)$ for the Si:P and $2p_{\pm} \rightarrow 1s(E)$ for the Si:Bi. The latter yields a value of the binding energy for the $1s(E)$ state in the Si:Bi of 30.14 meV. The temporal behavior of stimulated emission pulse from the Si:Bi suggests that multi-valley phonon processes are involved. This requires further investigation. We conclude that far and mid-infrared emission from intracenter optical transitions can be obtained in a number of elemental semiconductors and compounds doped by shallow impurities.

Mobility of interstitial B in Si analyzed by a stochastic reorientation model

B. Ittermann*, D. Peters, M. Füllgrabe, F. Kroll, H. Ackermann, H.-J. Stöckmann

Fachbereich Physik und Zentrum für Materialwissenschaften der Philipps Universität Marburg, D-35032 Marburg, Germany

Abstract

A density-matrix-based formalism is presented to extract activation parameters for the reorientational motion of an interstitial B defect in Si, a center created by ion implantation. β -radiation detected nuclear magnetic resonance (β -NMR) data show beginning mobility at $T \approx 240$ K. At $T = 410$ K the signal is lost even though the center is still present. The activation energy for its reorientation in p-type Si is determined to be $E_A = 0.53(2)$ eV. © 2001 Elsevier Science B.V. All rights reserved.

PACS: 61.72.Tt; 66.30.Jt; 82.56.Lz

Keywords: Si; Boron; Ion implantation; Diffusion; β -NMR

1. Introduction

Doping by ion implantation is state of the art in Si device technology. In order to model the final dopant distributions during and after the subsequent annealing step, precise diffusion data of the involved impurities and defects are needed. Conventionally, this information is obtained by various types of tracer experiments, where diffusion profiles are measured and analyzed. However, this access has limitations. First, these experiments are often restricted to high temperatures. Second, the information represented by a diffusion profile is a somewhat “integral” one, in the sense that the individual diffusing atom cannot be monitored directly in its jump process, but only the combined result of the motion of all involved species. It is very desirable, therefore, to supplement the profiling data by *spectroscopic* information on the details of the diffusion process.

In this paper we want to describe a stochastic model developed to extract quantitative activation parameters for the reorientational motion of an interstitial B center

in Si. This defect is created by ion implantation and observed for $T = 30$ – 410 K. Although the model was developed specifically for the interpretation of β -radiation detected nuclear magnetic resonance (β -NMR) spectra, it should be easily adaptable to any other magnetic resonance technique.

The first β -NMR observation of the interstitial B defect in question, labeled B_i in the following, was reported in Refs. [1,2] after implantation of ^{12}B in Si. It is diamagnetic and observed in p-type, intrinsic, and weakly n-type, but not in n^+ Si. Its symmetry is not higher than C_{3v} and it is characterized by an axially symmetric electric field gradient (EFG) with a quadrupolar coupling constant of $e^2qQ/h = -360(15)$ kHz. Later on, the marked temperature dependence of the B_i -signal intensity in differently doped samples was investigated by Frank et al. [3] and qualitatively explained as a reorientational motion of the center, i.e., a change of the defect axis from one $\langle 111 \rangle$ direction to another. There is experimental evidence, but no final proof, that this reorientation is the elementary step of a true migration through the lattice. The B_i diffusion parameters provide important clues, therefore, to the understanding of the so-called “transient enhanced diffusion” of implanted B in Si, a technologically important effect known to involve B_i migration [4].

*Corresponding author. Tel.: +49-6421-282-2559; fax: +49-6421-282-6535.

E-mail address: bernd.ittermann@physik.uni-marburg.de (B. Ittermann).

Several common properties suggest that the described β -NMR center is identical to the one discovered and described much earlier by Watkins and coworkers [5–8]. There, it was created by low-temperature electron irradiation of Si:B and characterized by EPR and DLTS. The assumption is that β -NMR and EPR measure the same defect in different charge states (positive and neutral, respectively). The question is not finally settled, however, and in the following we will not be concerned with the structure but only with the diffusion properties of the center.

2. Theory

Our goal is to calculate the nuclear polarization $P = \langle I_z \rangle / I\hbar$ via

$$\langle I_z \rangle = \text{Tr}(\rho I_z), \quad (1)$$

where ρ is the density matrix of our system which has to be determined. Its evolution in time is described by the Liouville equation

$$\dot{\rho} = \frac{1}{\hbar} [\rho, \mathcal{H}]. \quad (2)$$

The Hamiltonian under consideration can be written as

$$\mathcal{H} = \mathcal{H}_Z + \mathcal{H}_Q + \mathcal{H}_{\text{RF}}, \quad (3)$$

where the first two terms denote the nuclear Zeeman and quadrupole interaction and the last one the interaction of the spins with the RF field. We now turn to averages over the β lifetime, which are actually observed in our experiments

$$\bar{\rho} = \lambda \int_0^\infty \rho(t) \exp(-\lambda t) dt, \quad (4)$$

with $\lambda = 1/\tau_\beta$. Writing Eq. (4) for $\bar{\rho}$ instead of ρ we can partially integrate the right-hand side and obtain

$$\bar{\rho} = \lambda [\bar{\rho} - \rho(0)] = \frac{1}{\hbar} [\bar{\rho}, \mathcal{H}], \quad (5)$$

where $\rho(0)$ represents the known spin polarization at $t = 0$. If \mathcal{H} does not explicitly depend on time this can be rewritten as

$$\lambda [\bar{\rho} - \rho(0)] = \frac{1}{\hbar} [\bar{\rho}, \mathcal{H}] \equiv -iL\bar{\rho}. \quad (6)$$

The Liouville operator L , defined on the right-hand side of Eq. (6), is a matrix of rank $(2I + 1)^2$. Finally, we can rearrange Eq. (6) as

$$\bar{\rho} = (\lambda + iL)^{-1} \lambda \rho(0). \quad (7)$$

For a single Hamiltonian, i.e., one specific orientation of our defect center, Eq. (7) is the solution of our problem. It represents a simple linear equation system, which can be solved numerically. The main advantage of this special formulation is, however, that it can easily be

extended to include stochastic jumps between different configurations, i.e., Hamiltonians.

In case of N possible defect states we can write

$$\rho = \sum_{k=1}^N \rho_k. \quad (8)$$

The equation of motion including jump processes then reads

$$\dot{\rho}_j = -iL\rho_j - \sum_{k \neq j} (w_{jk}\rho_j - w_{kj}\rho_k), \quad (9)$$

where w_{jk} is the jump frequency from site j to site k . In our specific C_{3v} case we have $N = 4$ and all exchange jumps are equivalent. Therefore, we can replace the w_{jk} by one common rate w , which we assume to be thermally activated according to $w(T) = w_0 \exp(-E_A/k_B T)$.

Using the abbreviation $\tilde{L}_k = 3w + \lambda + iL_k$ we arrive at the final master equation

$$\begin{pmatrix} \tilde{L}_1 & -w & -w & -w \\ -w & \tilde{L}_2 & -w & -w \\ -w & -w & \tilde{L}_3 & -w \\ -w & -w & -w & \tilde{L}_4 \end{pmatrix} \begin{pmatrix} \bar{\rho}_1 \\ \bar{\rho}_2 \\ \bar{\rho}_3 \\ \bar{\rho}_4 \end{pmatrix} = \lambda \begin{pmatrix} \rho_1(0) \\ \rho_2(0) \\ \rho_3(0) \\ \rho_4(0) \end{pmatrix}. \quad (10)$$

Substituting Eq. (10) into Eq. (1) and implementing a linear-equation solver into a standard least-squares algorithm, we can fit the calculated $P(T)$ values directly to our data. Since all Hamiltonians are determined by experiment, we have only three free fit parameters: w_0 , E_A , and a common amplitude factor.

So far, we have assumed a stationary Hamiltonian which is inappropriate, of course, for the RF term of Eq. (3). The time dependence of \mathcal{H}_{RF} is usually eliminated by going to a rotating coordinate system. This requires a first-order treatment of \mathcal{H}_Q , however, and therefore neglects all spin-lattice relaxation effects due to the reorientational fluctuations of its off-diagonal elements. Since this can be a very effective relaxation mechanism, such a limitation is not always acceptable. To overcome this problem we stick to an exact treatment of \mathcal{H}_Q in laboratory coordinates and use the fact that \mathcal{H}_{RF} contains only one single frequency ω .

We extend our former equation of motion to

$$\lambda[\rho - \rho(0)] = (-iL_0 + W)\rho + L_1(e^{i\omega t} + e^{-i\omega t})\rho, \quad (11)$$

where the first and second terms on the right-hand side represent the stationary and the time-dependent contribution to \mathcal{H} , respectively. ρ is the lifetime-averaged (the bar has been dropped for better readability) density matrix representing all different lattice sites and W is the jump matrix containing all w terms of Eq. (10). ρ is expanded in a Fourier series

$$\rho = \sum e^{i n \omega t} \rho^n(t) \quad (12)$$

and by collecting coefficients we obtain

$$\lambda[\rho^n - \rho^n(0)] = [-i(L_0 - n\omega) + W]\rho^n + L_1(\rho^{n-1} + \rho^{n+1}), \quad (13)$$

where $\rho^n(0) = \delta_{n,0}\rho(0)$. Now we discard all higher orders of \mathcal{H}_{RF} and keep only $n = -1, 0, 1$. Physically, this means that multi-quantum transitions, the simultaneous absorption of two or more RF quanta, are neglected. This way, we obtain our final expression

$$\begin{aligned} \lambda\rho^1 &= [-i(L_0 - \omega) + W]\rho^1 + L_1\rho^0, \\ \lambda\rho^0 &= [-iL_0 + W]\rho^0 + L_1(\rho^{-1} + \rho^1) + \lambda\rho(0), \\ \lambda\rho^{-1} &= [-i(L_0 + \omega) + W]\rho^{-1} + L_1\rho^0, \end{aligned} \quad (14)$$

an equation system with additional couplings by the L_1 terms, three times larger than Eq. (10) but still quite manageable on modern workstations.

3. Experimental

A 1.5-MeV deuteron beam is used to produce radioactive ^{12}B probe nuclei (lifetime $\tau_\beta = 29.4$ ms, spin $I = 1$). A spin-polarized sub-ensemble is collected by recoil-angle selection and continuously implanted in the samples. The wide-spread recoil energies of ~ 0 –500 keV result in a flat implantation profile with $d_{\text{max}} \approx 1.2$ μm . In radioactive equilibrium we have about 2×10^4 ^{12}B nuclei simultaneously in the sample, which is kept in a magnetic field B_0 and can be exposed to a depolarizing (RF) field B_1 . The lifetime-averaged ^{12}B polarization is detected from the north/south asymmetry of the β -ray angular distribution (“ β asymmetry”). More experimental details of implantation β -NMR can be found, e.g., in Ref. [9].

The m substates of the ^{12}B spins are populated like $p_1 : p_0 : p_{-1} \approx 0.4 : 0.3 : 0.3$ under our experimental conditions, a rather accidental result of recoil polarization. In consequence, we cannot detect any ($m = 0 \leftrightarrow -1$) transitions in our RF scans.

4. Measurements and results

In Fig. 1 we plotted the amplitude of one B_i resonance in p-Si (10^{18} B/cm 3) vs. temperature. The data were measured in a slow temperature sweep (1 K/min) by irradiating the resonance of the low-frequency doublet of quadrupole satellites (see the inset of Fig. 1). The RF was on/off modulated at a rate of 0.25 s $^{-1}$ and the rf-induced polarization change was recorded. The crystal orientation was $\langle 110 \rangle \parallel B_0$, where the defect orientations are pairwise equivalent. A frequency modulation of ± 20 kHz was applied to ensure complete depolariza-

Fig. 1. Temperature dependence of the B_i -resonance intensity in p-type Si. $B_0 = 0.4$ T, $\langle 110 \rangle \parallel B_0$. $B_{1,\text{rot}} = 0.22$ mT, ± 20 kHz FM. The inset shows a spectrum of the center (for B_0 close to $\langle 100 \rangle$), the central line is due to substitutional B. The detected resonance is indicated by the double arrow. The solid line is a fit of the stochastic reorientation model. See text for more details.

tion even in the presence of an inhomogeneous broadening or a slight misalignment of the crystal.

Qualitatively, the figure shows three temperature regimes. At low temperatures, B_i is immobile and the detected signal is small since only two out of four defect orientations are detected. At $T \approx 240$ K, we have one reorientational jump per τ_β . The signal increases in the following since now *all* interstitial ^{12}B becomes (sooner or later) resonant at the irradiated frequency. The subsequent decrease for $T > 310$ K has two reasons: (i) the reorientation is so fast now, that the RF can no longer saturate the resonance, and (ii) the aforementioned spin–lattice relaxation which unavoidably accompanies the reorientation process.

The solid line in Fig. 1 is a fit of the formalism described in Section 2. It assumes the B_i fraction to be constant over the whole temperature range and describes the data well. Especially the signal loss for $T \gtrsim 400$ K has nothing to do with a disappearance of the defect, we are simply no longer able to detect it. For the B_i reorientation we obtain the following parameters:

$$w_0 = 10^{11.7(3)} \text{ s}^{-1}, \quad E_A = 0.53(2) \text{ eV}.$$

We would like to point out that an Arrhenius ansatz for B_i reorientation is justified only in p $^+$ -Si. It was shown in Ref. [3] that in intrinsic or n-type material the reorientation rates are enhanced by charge-state cycling. An implementation of Shockley–Read–Hall recombination rates into our formalism is straightforward and currently underway.

Stress-induced splitting of the electronic level related to a platinum–hydrogen complex in silicon

K. Fukuda*, Y. Iwagami, Y. Kamiura, Y. Yamashita, T. Ishiyama

Faculty of Engineering, Okayama University, Tsushima-naka 3-1-1, Okayama 700-8530, Japan

Abstract

We have applied deep-level transient spectroscopy (DLTS) under uniaxial compressive stress to study the structure of a platinum- and hydrogen-related defect, which has a gap state at 0.14 eV below the conduction band minima in Si. The application of $\langle 100 \rangle$ and $\langle 111 \rangle$ stresses split the DLTS peak of the defect into two components with intensity ratios of 2.7:1 and 1.4:1, respectively, which were the ratios of the low-temperature peak to the high-temperature peak. Under $\langle 110 \rangle$ stress, this peak split into three components as an intensity ratio of two lower-temperature peaks to the high-temperature peak was 1.4:5:1. In addition, we observed the stress-induced alignment of the defect to the configuration corresponding to the low-temperature DLTS peak during the DLTS scan in the temperature range of 65–100 K, for all stress directions. Our results provide the first evidence to connect the electronic level at $E_c - 0.14$ eV to the atomic configuration of the Pt–H₂ complex with the C_{2v} symmetry previously identified by EPR. © 2001 Elsevier Science B.V. 1. Introduction

Hydrogen is widely known to interact with transition-metal (TM) impurities in silicon and form various TM–hydrogen complexes. As a result, hydrogen causes the passivation of TM impurities or gives rise to new electronic states in the bandgap. In most cases, these complexes have been detected by deep-level transient spectroscopy (DLTS) since their formation often results in the appearance of new electronic levels [1–4], or the disappearance of the deep levels related to TM impurities. DLTS is useful to investigate the properties of electronic levels related to TM–hydrogen complexes, but provides no information about their structures. On the other hand, electron paramagnetic resonance (EPR) is a powerful technique to study the electronic states and

atomic configurations of complexes. However, EPR cannot make the exact determination of their electronic levels. Thus, there have often been some missing rings of a chain to connect the electronic states of defect complexes to their structural information.

Using DLTS under uniaxial stress, termed as stress DLTS, we can obtain more detailed microscopic information, which is not given by standard DLTS. If the electronic state of a defect whose symmetry is lower than that of the host crystal is orbitally singlet, the stress may lift its orientational degeneracy. In stress DLTS, this is observed as the splitting of a DLTS peak, and the relative intensities of the split peak components reflect the symmetry of the defects [5].

One of typical TM impurities, platinum, in Si has been known to form various hydrogen-involved complexes to produce deep levels in the bandgap. Among such complexes, one complex (Pt–H₂) involving two hydrogen atoms was identified by EPR combined with infrared (IR) absorption spectroscopy under uniaxial stress [6]. A recent DLTS study using depth profiling

technique has proposed the determination of the number of hydrogen atoms involved in various platinum–hydrogen complexes [4], and has concluded that the complex having the electronic level at $E_c - 0.18$ eV is Pt–H₂ identified by EPR. Direct evidence is, however, still lacking.

In the present paper, we report on the first attempt to apply stress DLTS technique to study the structure of a platinum- and hydrogen-related complex, which has an electronic level at $E_c - 0.14$ eV. Considering the intensity ratios of split peaks under $\langle 100 \rangle$, $\langle 111 \rangle$ and $\langle 110 \rangle$ stresses and the stress-induced alignment of the complex observed during the DLTS scan, we determine the symmetry of the complex as C_{2v} and provide the first evidence to connect the electronic level at $E_c - 0.14$ eV to the atomic configuration of the Pt–H₂ complex previously identified by EPR.

2. Experimental procedure

We used n-type FZ silicon crystal ingots, which had a phosphorus density of $5.9 \times 10^{14} \text{ cm}^{-3}$. For stress experiments, many samples were cut from the ingots into square pillars with dimensions of $1 \times 1 \times 6 \text{ mm}^3$, the longest of which was parallel to the $\langle 111 \rangle$, $\langle 110 \rangle$ or $\langle 100 \rangle$ direction. Platinum was evaporated on one side of the samples, which were subsequently annealed at 850°C for 2 h in an argon atmosphere for the indiffusion of platinum. After the diffusion, the platinum-evaporated face of the samples was mechanochemically polished to remove the platinum remaining on the surface. Hydrogen was injected into the platinum-diffused samples by chemical etching (HF:HNO₃:CH₃COOH = 1:2:1) before the fabrication of Schottky contacts, which were formed by vacuum evaporation of gold on the polished and etched surface. Capacitance DLTS measurements were performed with a reverse bias of 5 V and a filling pulse of 5 V at rate windows of $116\text{--}928 \text{ s}^{-1}$ under uniaxial compressive stress of 0.6–1.0 GPa applied to the samples along their longest dimension. The stress was applied to the samples at the minimum temperature (typically 63 K) at which the DLTS scan started, and was held during the DLTS run up to 100 K and above.

3. Results

A typical DLTS spectrum taken at an emission rate $e_t = 116 \text{ s}^{-1}$ is shown in Fig. 1. Two dominant peaks, labeled E1 and Pt, appears at 85 and 125 K, respectively, and two small peaks, labeled E2 and E3, are seen at 160 and 270 K, respectively. The electronic levels and the electron-capture cross sections of these peaks are listed in Table 1. The activation energy and the

Fig. 1. DLTS spectrum recorded at an emission rate $e_t = 116 \text{ s}^{-1}$ of platinum-doped n-type silicon. No stress was applied during the DLTS scan. The energy levels and electron capture cross sections of the peaks are listed in Table 1.

electron-capture cross section of the Pt peak agree with those reported to be assigned to the acceptor level (Pt⁻⁰) of substitutional platinum [3]. The activation energies of E1 and E3 peaks are comparable with those of two Pt- and H-related levels reported in the literature [3,4], where they are labeled E(90) and E(250), respectively. We therefore tentatively assign these three peaks as indicated in Table 1. The E2 was detected in all of our samples, while it has not been reported so far. So, we conclude that the E2 peak is due to an unidentified defect unique to our Si crystal and experimental procedure. In the present work, we concentrate our attentions on the stress-induced peak splitting of the E1 peak.

Fig. 2 shows the DLTS spectra of the E1 peak recorded under uniaxial stresses along with $\langle 111 \rangle$ (a), $\langle 100 \rangle$ (b), and $\langle 110 \rangle$ (c) directions, shown by solid curves. In Fig. 2(b) and (c), dashed curves represent the fitting using the usual DLTS function and dotted curves represent spectra recorded under no stress, while these curves are not shown in Fig. 2(a) for legibility. Under compressive stresses along the $\langle 111 \rangle$ and $\langle 100 \rangle$ directions, we observed clear splitting of the E1 peak into two components, as shown in Fig. 2(a) and (b). In Fig. 2(b), the emission rate is increased to 1856 s^{-1} to shift the split peaks toward high temperatures, which are higher than the lowest attainable temperature (63 K) in our DLTS system. From the fitting, we have determined that the intensity ratios of low- to high-temperature split peaks is 1.4:1 for $\langle 111 \rangle$ stress, and 2.7:1 for $\langle 100 \rangle$ stress. Under a $\langle 110 \rangle$ stress, we obtained that the E1 peak split into three components as shown in Fig. 2(c) by increasing the emission rate to 4332 s^{-1} . From the fitting, we have determined that the intensity ratio of lower- to high-temperature split peaks is 1.4:5:1 for $\langle 110 \rangle$ stress. In addition, we observed an interesting feature that the second DLTS scan produced a quite different spectrum

Table 1

Energy levels and capture cross sections of the deep levels shown in Fig. 1

Label	Activation energy (eV)	Capture cross section (cm^2)	Assignment
E1	$E_c - 0.14$	9×10^{-16}	Pt–H related
Pt	$E_c - 0.22$	1×10^{-15}	Pt ⁰
E2	$E_c - 0.27$	5×10^{-16}	Unidentified
E3	$E_c - 0.55$	5×10^{-15}	Pt–H related

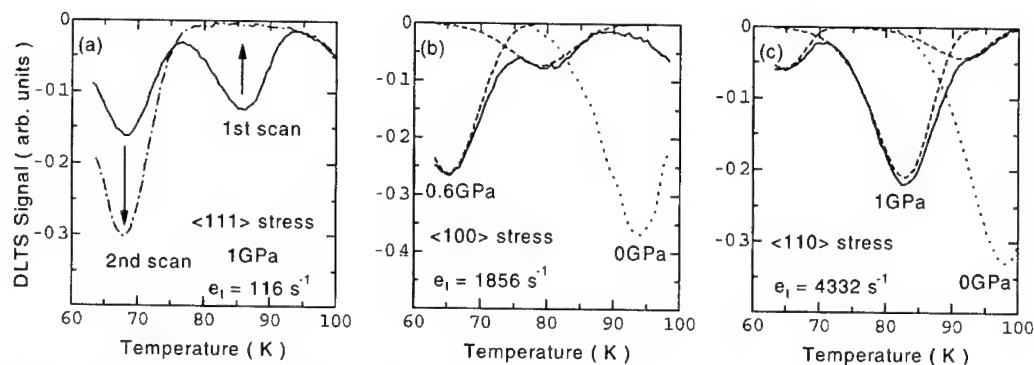

Fig. 2. DLTS spectra of the E1 peak due to a Pt- and H-related complex in Si under uniaxial compressive stresses. Solid curves indicate the spectra recorded at $e_1 = 116 \text{ s}^{-1}$ under a stress of 1 GPa along with the $\langle 111 \rangle$ direction (a), at $e_1 = 1856 \text{ s}^{-1}$ under a stress of 0.6 GPa along the $\langle 100 \rangle$ direction (b), and at $e_1 = 4332 \text{ s}^{-1}$ under a stress of 1 GPa along the $\langle 110 \rangle$ direction (c). In (b) and (c), dashed curves represent the fitting using the usual DLTS function and dotted curves represent spectra recorded under no stress, while these curves are not shown in (a) for legibility. In (a), a solid curve was recorded by the first DLTS scan, and a dashed-dotted curve was recorded by the second scan.

(the dashed-dotted curve in Fig. 2(a)), where the low-temperature peak increases with correlated decreasing of the high-temperature peak. This strongly suggests that the stress-induced alignment of the defect to the configuration corresponding to the low-temperature DLTS peak occurred during the two DLTS scans in the temperature range of 65–100 K. We also observed similar signature in the spectra taken by the second DLTS scan under both $\langle 100 \rangle$ and $\langle 110 \rangle$ stresses.

4. Discussion

Uniaxial stress generally splits not only a defect level but also the conduction band. Since DLTS detects the thermal emission of an electron from the defect level to the conduction band, we substantially observe the energy difference between all of the split defect levels and the lowest-energy component of the split conduction band. Therefore, DLTS-peak splitting is due to the splitting of the defect level. If the ground state of the defect is a singlet with a symmetry lower than that of the host lattice, the peak splitting results from the lift of orientational degeneracy of the defect and reflects the symmetry of the defect. From theoretical consideration, Kaplyanskii summarized the multiplicity of orienta-

tional degeneracy for all the possible defect symmetries in a cubic lattice, together with the number of components of the splitting and the residual multiplicity of orientational degeneracy under $\langle 100 \rangle$, $\langle 110 \rangle$ and $\langle 111 \rangle$ stresses [7]. Only the rhombic-I symmetry is consistent with our results in view of the number of components of the splitting, though the residual multiplicity of orientational degeneracy does not completely agree with the intensity ratios of split DLTS peaks. However, if we consider that the stress-induced alignment of the defect to the configuration corresponding to the low-temperature DLTS peak occurs during the DLTS scan, the intensity ratios of split DLTS peaks before the alignment should be 3:3, 1:4:1 and 4:2 for $\langle 111 \rangle$, $\langle 110 \rangle$ and $\langle 100 \rangle$ stress directions, respectively. Among all rhombic-I centers, only those with C_{2v} symmetry are possible in the lattice with T_d symmetry. Therefore, we conclude that the defect responsible for the E1 peak has C_{2v} symmetry and is identified as the Pt–H₂ complex previously observed by EPR.

5. Conclusions

We have applied DLTS under uniaxial compressive stress up to 1 GPa to study the structure of a

platinum- and hydrogen-related defect, which has an energy level at $E_c - 0.14\text{eV}$ in Si. The application of $\langle 100 \rangle$ and $\langle 111 \rangle$ stresses split the DLTS peak into two components with intensity ratios of 2.7:1 and 1.4:1, respectively, which were the ratios of the low-temperature peak to the high-temperature peak. Under $\langle 110 \rangle$ stress, this peak splits into three components as the intensity ratio of two lower-temperature peaks to the high-temperature peak is 1.4:5:1. In addition, we observed that repeated DLTS scans at 63–150 K under uniaxial stresses induced the low-temperature peak to grow with decaying high-temperature peak. This observation implies that the defect was aligned under applied stresses to the configuration corresponding to the low-temperature DLTS peak. Considering the influence of stress-induced alignment on the intensity ratios of split DLTS peaks, we have determined that the defect has the C_{2v} symmetry, which should have such ratios of orientational degeneracy as 4:2 under $\langle 100 \rangle$ stress, 1:4:1 under $\langle 110 \rangle$ stress and 3:3 under $\langle 111 \rangle$ stress. Therefore, we have identified our DLTS peak as arising from the Pt-H₂ complex previously identified by EPR. Thus, our results provide the first experimental evidence to connect the atomic configuration of the Pt-H₂ complex to its electronic state and also evidence for its stress-induced alignment.

Valence force field analysis on nitrogen in silicon

H. Harada*, I. Ohkubo, T. Mikayama, Y. Yamanaka, N. Inoue

RIAST, Osaka Prefecture University, 1-2 Gakuencho, Sakai, Osaka 599-8570, Japan

Abstract

Nitrogen doping attracts attention because it reduces void defects drastically. But the mechanism has not been clarified yet. Various configurations of nitrogen have been proposed by using the first principles calculation but there is no description how the stress plays a role in determining these nitrogen configurations. We reveal normal vibration modes corresponding to well-known infrared absorption peaks at 766 and 963 cm⁻¹ of nitrogen split interstitial (N–N) and derive force constants for bond stretching and bond bending. Local strain energy near nitrogen is calculated for the optimized structures of N–N, nitrogen–vacancy complex, substitutional N and interstitial N. As a result, it is found that in structures of N–N and N₂–V₂ with filled electron orbitals, strain energy plays an important role in the determination of the stable structure. © 2001 Published by Elsevier Science B.V.

Keywords: Nitrogen; Silicon; Molecular orbital; Valence force; Infrared absorption

1. Introduction

Nitrogen doping has attracted much attention because it reduces void defects drastically. But the mechanism has not been clarified yet. There are two important nitrogen configurations, split interstitial N pair (N–N complex) [1] and N₂–V_x complexes at high temperature [2]. The N–N complex is considered to be related to the infrared absorption peaks at 766 and 963 cm⁻¹ and N₂–V_x complexes are related to void defect formation. Stress within these configurations plays an important role in determining detailed atomic configuration and defect formation. We have studied the role of stress in the defect formation and point defect kinetics in silicon crystals by the continuum elasticity treatment [3]. For the case of nitrogen which mainly locates in interstitial site, the valence force treatment seems to be a better way to reveal the atomic level behavior related to stress. However, in the cases of substitutional nitrogen it was reported to be unsuccessful [4]. We have made a preliminary study on nitrogen configuration determination using the force constants of

silicon, because there have been no reliable data for Si–N [5]. Valence force analysis on interstitial oxygen has succeeded in explaining the infrared absorption spectrum. In this study, we clarify the normal vibration modes of N–N complex by the semi-empirical molecular orbital (MO) method. As a result, it is found that the well-known 766 and 963 cm⁻¹ peaks correspond to the antisymmetric stretching modes of H₂O-type nonlinear three-atom molecule and BF₃-type planar four-atom molecule. By using the relationship between force constants and frequencies of these normal vibrations, force constants of nitrogen–silicon bonds related to stretch component and bending component are determined. The strain energies of unrelaxed and optimized structures of N–N complex and N₂–V₂ complex are calculated by using these force constants. It is found that the strain energy plays an important role in the determination of optimized structure. The strain energy for substitutional nitrogen and interstitial nitrogen is also calculated and discussed.

2. Analysis

The semi-empirical MO method is employed for the calculation of stable structure, normal vibration mode

E-mail address: harada@riast.osakafu-u.ac.jp (H. Harada).

and vibration frequency of N–N complex. For this purpose, $\text{Si}_2\text{N}_2(\text{Si}_2\text{H}_5)_2(\text{SiH}_3)_4$ cluster including Si_2N_2 rectangle terminated by hydrogen was used as shown in Fig. 1. We used the program “MOPAC2000” and MNDO-d (modified neglect of diatomic overlap with d-orbital) Hamiltonian is adopted under a precise convergent condition.

Using the valence force field model [6] we can estimate the atomic-level strain energy for the present cases. Keating defined the quantity λ_{mn} satisfying the translational invariance and the rotational invariance of strain energy as follows:

$$\lambda_{mn} = \frac{\mathbf{x}_m \cdot \mathbf{x}_n - \mathbf{X}_m \cdot \mathbf{X}_n}{2a}, \quad (1)$$

where \mathbf{X} and \mathbf{x} indicate displacements before and after deformation and a is lattice constant as shown in Fig. 2. Stretch component E_α and bending component E_β of strain energy are given by the following equations:

$$E_\alpha = \frac{1}{2} \alpha \sum_{m,n=1} \lambda_{mn}^2, \quad (2)$$

$$E_\beta = \beta \sum_{m=1, n>m} \lambda_{mn}^2. \quad (3)$$

α and β denote force constants related to stretch and bending, respectively. These are found as 194.1 and 55.28 N/m in crystalline silicon. Infrared absorption normal modes of molecules are generally analyzed using the valence force, and this is applicable to local vibrational mode of impurities as confirmed in the case of oxygen, in which the above force constants are obtained by solving the equation between the frequencies of normal mode of molecule and the force constants. In the case of H_2O , the equation between the vibrational frequencies of the antisymmetric stretch

Fig. 2. Schematic of valence force treatment. Introduced quantity satisfies translation invariance and rotational invariance. \mathbf{X} and \mathbf{x} denote displacements before and after deformation.

mode and the stretch force constant is

$$4\pi^2 v^2 = \left(1 + \frac{2m_H}{m_O} \sin^2 \theta\right) \frac{\alpha}{m_H}, \quad (4)$$

where v is frequency, m and θ denote mass of species and half of the bond angle, respectively. In contrast, in the case of BF_3 ,

$$4\pi^2 (v_{AS}^2 + v_{AB}^2) = \left(1 + \frac{3m_F}{2m_B}\right) \left(\frac{\alpha}{m_F} + \frac{3\beta}{m_F}\right), \quad (5)$$

$$16\pi^4 v_{AS}^2 v_{AB}^2 = 3 \left(1 + \frac{3m_F}{m_B}\right) \frac{\alpha\beta}{m_F^2}. \quad (6)$$

Suffix AS and AB mean antisymmetric stretch vibration and antisymmetric bending vibration.

By using these force constants, we estimate strain energies within the third nearest silicon from nitrogen, in N–N complex, $\text{N}_2\text{--V}_2$ complex, substitutional nitrogen and interstitial nitrogen for optimized structures and initial structures as shown in Figs. 3 and 4. Small and large spheres represent nitrogen and silicon, respectively. In the initial structures, all silicon atoms are located at the lattice points as shown in Fig. 4. The role of stress in determining the optimized structures by the amount of change of strain energy from the initial structures to the optimized structures is discussed. The change of strain energy due to optimization is traced by rotating the line between Si atoms in the case of N–N complex and by changing Si–N–Si bond angle in the case of $\text{N}_2\text{--V}_2$ complex as shown in Fig. 4. For simplicity, the shape of Si_2N_2 is fixed and it is rotated to the position proposed by Jones [1].

3. Result and discussion

The atomic vibrational displacements of Si_2N_2 structure corresponding to strong infrared absorption near 766 and 963 cm^{-1} are found by the force calculation of

Fig. 3. Optimized structures of (a) N–N complex, (b) N_2 – V_2 complex, (c) interstitial nitrogen and (d) substitutional nitrogen. Small white, gray and black spheres represent nitrogen, relaxed silicon and silicon on sites, respectively.

Fig. 4. Initial structures of (a) N–N complex (b) N_2 – V_2 complex. All silicon atoms are located at the lattice sites. Structure optimization is performed by rotating the broken line connecting Si–Si in N–N complex and by changing Si–N–Si bond angle in N_2 – V_2 complex.

$Si_2N_2(Si_2H_5)_2(SiH_3)_4$ cluster as shown in Fig. 5. Each displacement consists of antisymmetric stretch vibration of an H_2O -type nonlinear three-atom molecule and a BF_3 -type planar four-atom molecule, as expected. These wavenumbers are 750 and 943 cm^{-1} , close to the well-known 766 and 963 cm^{-1} related to N–N complex and transition dipoles of these vibrations are relatively higher than that of other modes. Thus, these vibration modes are considered to correspond to the observed 766 and 963 cm^{-1} peaks, respectively.

Thus, by solving Eq. (4) for the antisymmetric stretch vibration of the H_2O -type nonlinear three-atom molecule whose wavenumber is 766 cm^{-1} and (5) and (6) for the BF_3 -type planar four-atom molecule at 963 cm^{-1} , the force constants α and β are obtained to be 330 and

Fig. 5. Atomic displacements of N–N complex corresponding to normal vibration modes of (a) 750 and (b) 943 cm^{-1} .

29 N/m. There has been no successful report about force constants associated with nitrogen in crystalline silicon. In amorphous Si implanted with nitrogen and annealed, these values are reported as 227 and 9.2 N/m [7]. The present results are bigger than the reported ones, probably due to the stronger bonds in crystal than in amorphous structure.

Next, changes of strain energy accompanying structure deformation are calculated. As for N–N complex, the strain energy is plotted against the rotation angle as shown in Fig. 6. As for N_2 – V_2 complex, N atoms are located at the lattice points for the initial configuration (the unit shape is like that of nonplanar NH_3) while they are located where Kageshima proposed by the first principles calculation (the unit shape is like that of planar BF_3) [2]. It is found that in both cases, the optimized structure minimizes its strain energy. Thus, in both cases it is concluded that the strain energy plays an important role in determining the detailed atomic configuration. Table 1 summarizes strain energy for initial structures and optimized structures.

In cases of substitutional nitrogen and interstitial nitrogen, strain energy increases for optimization. It is to be noted that there is an odd electron in both cases, in contrast to the cases of N–N and N_2 – V_2 where no unbonded electron exists. Thus, it is considered that the charge effect rather than the stress effect determines these atomic configurations. Unsuccessful valence force treatment on substitutional nitrogen by Hjalmarsen was due to this charge effect.

4. Summary

Normal vibrational modes of nitrogen interstitial pair (N–N) are clarified by the MO calculation to be antisymmetric stretches of a BF_3 -type planar four-atom molecule and an H_2O -type nonlinear three-atom molecule, for observed peaks at 963 and 766 cm^{-1} , respectively. By solving the equation for the relation of vibrational frequencies and force constants, stretch and bending force constants of Si–N bonds are determined. By using these force constants, strain energy changes from the unrelaxed structures to the optimized structures are calculated for the N–N, N_2 – V_2 substitutional

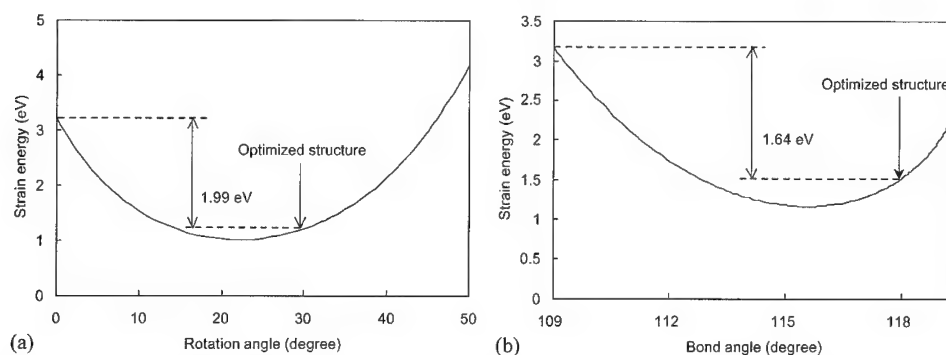

Fig. 6. Change of strain energy accompanying optimization for (a) N–N complex and (b) N₂–V₂ complex.

Table 1
Change of strain energy for initial structure and optimized structure

	Initial structure	Optimized structure (eV)
N–N	3.21	1.22
N ₂ –V ₂	3.17	1.53
Ns	2.10	3.39
Ni	0.537	0.561

nitrogen and interstitial nitrogen. In N–N and N₂–V₂ complexes, the optimized structure has the minimum strain energy, showing that the strain energy determines the detailed atomic configuration. In contrast, in interstitial and substitutional nitrogen, it is found that strain energy increases on optimizing the structure, suggesting that the charge effect is more important. It is concluded that in the case of closed structures strain energy plays an important role whereas in the case of structures with a lone electron, charge effect plays a more important role.

Spectroscopic characterization of implanted boron in microcrystalline silicon by β -NMR

F. Mai, B. Ittermann*, M. Füllgrabe, M. Heemeier, F. Kroll, K. Marbach, P. Meier, H. Mell, D. Peters, H. Thieß, H. Ackermann, H.-J. Stöckmann

Abstract

Spin-polarized, radioactive ^{12}B probe nuclei were implanted in microcrystalline Si with typical grain diameters of ~ 10 nm. Using β -radiation detected nuclear magnetic resonance (β -NMR) we observed broad, unstructured spectra at room temperature. This broadening is shown to be due to structural disorder. It is not caused by hydrogen or other contaminations of the samples. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Hydrogenated, microcrystalline Si ($\mu\text{c-Si:H}$) is used as a contact and substrate material in thin-film technology [1]. Its main advantage is the possibility of a cost-effective deposition in large areas. Considering applications, e.g., solar cells, $\mu\text{c-Si:H}$ is therefore a direct competitor to amorphous Si (a-Si:H). In this comparison it is hoped that the microcrystalline modification will show less degradation, better doping efficiency, higher carrier mobility, and, due to the lower band gap, better absorption in the near infrared.

Despite its historical name, $\mu\text{c-Si:H}$ is a material with nm-length scales. Compared to conventional polycrystalline solids its properties are influenced by a relatively high volume fraction of grain boundaries and open volumes. Additionally, the sample properties are affected by a hydrogen content of several at%, incorporated during deposition.

p-type doping of $\mu\text{c-Si:H}$ films is usually achieved in the deposition process by adding a certain amount of B_2H_6 to the process gas. We applied ion implantation, however, as an alternative approach to introduce B atoms into the samples after growth. In the present study we report a structural characterization of B in $\mu\text{c-Si:H}$ by means of β -radiation detected nuclear magnetic resonance (β -NMR).

2. Experimental

Radioactive ^{12}B (lifetime $\tau_\beta = 29.4$ ms, spin $I = 1$) is produced in the nuclear reaction $^{11}\text{B}(\text{d}, \text{p})^{12}\text{B}$ using a primary beam of 1.5-MeV deuterons. Spin-polarized probe nuclei are collected by recoil-angle selection and continuously implanted in the samples with wide-spread recoil energies from ~ 0 to 500 keV. This results in a quite homogeneous implantation profile with a maximum depth of $d \approx 1.2$ μm . In radioactive equilibrium we have only about 2×10^4 ^{12}B nuclei simultaneously in the sample. The sample is kept in a magnetic field B_0 and can be exposed to a depolarizing radio-frequency (RF) field B_1 . The lifetime-averaged ^{12}B polarization is detected from the north/south asymmetry of the β -ray

angular distribution. More experimental details are given in Ref. [2].

The nuclear polarization P in conventional NMR results from an almost linear variation of the m -substate population with m (Boltzmann polarization). This is markedly different in our case of recoil polarization. From previous studies we know our substate populations to be $p_1 : p_0 : p_{-1} \approx 0.4 : 0.3 : 0.3$. In consequence, we cannot detect any ($m = 0 \leftrightarrow -1$) transitions in our RF scans. A priori, there is no reason to expect the familiar symmetry of NMR spectra in our type of experiments.

Two-micrometer thick $\mu\text{-Si:H}$ films were deposited at $T = 280^\circ\text{C}$ by conventional plasma-enhanced chemical vapor deposition (PECVD) [1]. Structurally different samples were obtained by a variation of the SiH_4/H_2 ratio in the process gas. Raman spectroscopy was used to determine crystalline volume fractions of 76–87%. The difference to 100% is assumed to be due to grain boundaries [3]. The mean grain diameters, estimated from TEM and X-ray scattering data, were about 10 nm in films deposited with 1–5% SiH_4 in the process gas. The samples contained 2.5–5.5 at% H and were not intentionally doped.

3. Measurements and results

A β -NMR spectrum of ^{12}B in $\mu\text{-Si:H}$, measured at $T = 300\text{ K}$, is presented in Fig. 1. Almost identical data

were obtained in all samples investigated so far. Instead of one or more resolved resonances we find a broad frequency distribution with a full-width at half-maximum (FWHM) of $\sim 50\text{ kHz}$. This is in contrast to the situation in single crystalline Si, where, depending on the measuring conditions, linewidths below 1 kHz can be observed [4]. It is the main object of this paper to explore the nature of this broad spectrum.

In first-order perturbation theory, the energy of a given magnetic substate m of our ^{12}B spin $I = 1$ is given by

$$E_m = -h\nu_L m + \frac{e^2 q Q}{4I(2I-1)} \left(\frac{3}{2} \cos^2 \theta - \frac{1}{2} \right) (3m^2 - I(I+1)), \quad (1)$$

where $e^2 q Q$ is the so-called quadrupole coupling constant measuring the magnitude of the electric field gradient (EFG) at the ^{12}B position and θ is the angle between principal EFG axis and \mathbf{B}_0 (we assume an axially symmetric EFG tensor for simplicity).

The spectrum of Fig. 1 is centered at the Larmor frequency ν_L . It cannot be just the orientational averaging of Eq. (1) for one specific value of $e^2 q Q$, therefore. For ($\Delta m = 1$) transitions the peak of such a “powder pattern” would occur for $\theta = 90^\circ$ at $\nu = \nu_L + \frac{3}{8} e^2 q Q / h$. Due to our specific m substate population we would also observe a distinctly asymmetric spectrum. All this is clearly not the case in Fig. 1 and we can state

Fig. 1. Typical β -NMR spectrum of ^{12}B in $\mu\text{-Si:H}$ measured at $B_0 = 0.3\text{ T}$ and $T = 300\text{ K}$. The inhomogeneous frequency distribution has a full width at half maximum of $\sim 50\text{ kHz}$. In order to enhance the weak signals a frequency modulation of $\pm 10\text{ kHz}$ had been applied to measure this spectrum. The RF amplitude was $B_{1,\text{rot}} = 0.1\text{ mT}$. The solid lines are simulated spectra as explained in the text.

Fig. 2. (a) β -NMR spectrum of ^{12}B in $\mu\text{c-Si:H}$ measured with $B_{1,\text{rot}} = 0.29$ mT and without FM. $B_0 = 0.3$ T, $T = 360$ K. The sharp line in the center of the spectrum is due to a double-quantum (DQ) transition. All probe nuclei participate in this resonance, independent of their quadrupole shift. (b) A high resolution scan of the DQ line measured with reduced RF power ($B_{1,\text{rot}} = 0.12$ mT) at $T = 350$ K. The solid lines are simulated spectra as explained in the text.

that the observed distribution of NMR frequencies is not just the result of the polycrystallinity of the sample but reflects a corresponding distribution of ^{12}B defect states.

This is a surprising result, considering the high crystalline volume fractions in our samples. The β -NMR signatures of ^{12}B in crystalline Si (c-Si) are well known [4,5]: a Larmor resonance from substitutional B and a well-defined EFG [$e^2qQ/h = -360(15)$ kHz] from positively charged interstitial B. The data of Fig. 1 are distinctly different from what would have been obtained by just an orientational averaging of these c-Si features. The $\mu\text{c-Si:H}$ spectra are rather dominated by disorder which appears to be characteristic for this modification of Si.

Two possible sources could be responsible for the broadened β -NMR spectra: a distribution of local magnetic fields or of EFGs. The latter quantity measures the deviation of the local charge distribution from full cubic symmetry. Therefore, an EFG distribution reflects structural disorder. Magnetic disorder could be due to paramagnetic defects in the vicinity or due to the presence of H or other nearby impurities with non-vanishing magnetic moments. We can discriminate between these two possibilities with the help of Fig. 2. There we see another ^{12}B spectrum in $\mu\text{c-Si:H}$, this time recorded with higher RF power. The striking difference to Fig. 1 is the appearance of an additional, very sharp resonance just at ν_L , superimposed to the already known, broad spectrum. A higher-resolution scan of this new feature is depicted in Fig. 2(b). There we see that this line is only about 300 Hz wide and slightly asymmetric in shape.

From its unique dependence on RF power we can immediately identify the new signal as a so-called double quantum (DQ) resonance, where the ($m = \pm 1$) states are coupled directly by the simultaneous absorption of two RF quanta. The special properties of a DQ resonance compared to the normal ($\Delta m = 1$) ("single quantum", SQ) transition can be seen from Eq. (1). Both signals respond identically to magnetic disorder (a variation of ν_L) but the ($1 \leftrightarrow -1$) transition is (in first-order perturbation theory) not affected by the presence of an EFG.

Therefore, the sharpness of the experimentally observed DQ line excludes the presence of any magnetic broadening. This means, in turn, that only structural disorder is responsible for the wide distribution of SQ frequencies. From the residual DQ linewidth we can exclude the presence of H, N, or any other impurities carrying magnetic moments, in the vicinity of our ^{12}B probe nuclei.

Independent proof of an EFG is the observation of the ($\Delta m = 2$) resonance shown in Fig. 3. This transition from ($m = -1$) to ($m = +1$) by absorption of a single RF quantum is selection-rule forbidden and can only be observed in the presence of quadrupolar perturbation at rather low magnetic fields.

Both DQ and ($\Delta m = 2$) resonance had the familiar Lorentzian line shape if caused by a single, well-defined EFG. In our situation of an e^2qQ distribution we observe a corresponding broadening plus pronounced "distortions" of the experimental line shapes. These are second-order effects which are particularly important for the ($\Delta m = 2$) resonance of Fig. 3. In total, we can say that the ($\Delta m = 1$) spectrum (Figs. 1 and 2(a)), the DQ

Fig. 3. ($\Delta m = 2$) spectrum of ^{12}B in $\mu\text{-Si:H}$ measured without FM at a lower magnetic field of $B_0 = 0.1$ T. $B_{1,\text{rot}} = 0.33$ mT, $T = 330$ K. The sharp onset of the spectrum occurs at twice the Larmor frequency. The pronounced asymmetry reflects the interplay between EFG distribution and (weakened) RF selection rules and is theoretically understood (solid line, see text for details).

resonance of Fig. 2(b) and the ($\Delta m = 2$) spectrum (Fig. 3) all reflect the same EFG distribution. The different matrix elements for each type of transition lead to the spectral distributions of characteristically different shape and width.

In order to reproduce the experimental spectra we calculated the homogeneous β -NMR-line shape for each magnitude and orientation of a given EFG (for simplicity assumed to be axially symmetric) by means of a density-matrix formalism to be described elsewhere. Then we averaged these data over all crystal orientations and an assumed distribution of EFG magnitudes.

The central result of this simulation is that only a *unimodal* distribution centered at $e^2qQ = 0$ can reproduce the experimental findings. This means that full tetrahedral symmetry is still the most likely configuration and that prolate and oblate charge distortions are equally probable. In our simulations we assumed a Gaussian distribution of e^2qQ/h with a standard deviation of $\sigma = 150$ kHz. All the solid lines in Figs. 1–3 were consistently calculated from this distribution taking the varying experimental parameters (B_0 and RF conditions) correctly into account. The so-obtained simulated spectra agree quite well with the experimental data; especially the peculiar line shapes of the higher-order transitions are almost perfectly reproduced.

We would like to emphasize that the necessity to reproduce three different types of transitions simultaneously is a quite rigorous test of the assumed EFG distribution. In the case of ^{12}B in amorphous Si, for instance, we observed SQ spectra quite similar to the one

of Fig. 1, but a much more rounded ($\Delta m = 2$) spectrum. Those spectra could only be described [6] by a completely different, bimodal e^2qQ distribution with a *minimum* at $e^2qQ = 0$.

4. Summary

After room-temperature implantation of ^{12}B at negligible concentrations in hydrogenated, microcrystalline Si we observe broad and unstructured β -NMR spectra. From a combined analysis of single quantum, double quantum, and ($\Delta m = 2$) spectra it is concluded that these frequency distributions reflect structural disorder, i.e., ^{12}B nuclei in randomly distorted surroundings. Pairing of the implanted B with H or other contaminants in the samples can be excluded on grounds of the very narrow DQ resonances observed. Despite a crystalline volume fraction of $\geq 75\%$ in our samples we could not detect any signals corresponding to the known substitutional or interstitial B in Si.

Acknowledgements

We would like to thank D. Ruff for his assistance in the preparation and characterization of the samples and W. Fuhs for various discussions. We gratefully acknowledge the hospitality of the Strahlencentrum der Universität Giessen, where all β -NMR measurements were performed. This work was sponsored by the SFB 383 of the DFG and by the BMBF.

Abstract

Three species of a shallow donor family (D1–D3) have been observed previously with infrared absorption (FTIR) and electron paramagnetic resonance (EPR) in hydrogenated Czochralski-grown Si crystals after irradiation with fast electrons and subsequent annealing in the temperature range of 300–550°C. In a further detailed EPR investigation, we resolved a hyperfine (hf) interaction with one ²⁹Si nucleus and revealed thus the incorporation of one silicon atom in the defect core. The incorporation of one hydrogen (deuterium) atom in the core of the D1 and D2 centers was observed in electron nuclear double resonance. High resolution FTIR on ¹³C enriched samples showed the incorporation of one C atom in the core. By comparison of the optical and magnetic resonance spectra with those obtained previously for Si-NL10(H) and shallow thermal donors (STD(H)) it is concluded that D1 is the first species of the STD(H) and that the STD(H) defects and the NL10(H) defects are identical. These shallow donor types incorporate one hydrogen atom and, as an other impurity, C in nominally undoped Si or Al (NL10(Al)). An atomic model of the STD(H)/NL10(H) defects is presented. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Hydrogen; Shallow thermal donors; Magnetic resonance

1. Introduction

Upon heat treatment of oxygen-rich silicon at approximately 470°C two oxygen related defect centers show distinguishable absorption lines in Fourier transform infrared (FTIR) and photo thermal ionization spectroscopy. The centers were called thermal double donors (TDD) and shallow thermal donors (STD). They develop after annealing times of $t \approx 0.5$ and $t > 10$ h, respectively. The STDs appear with absorption bands in the range of 300–150 cm⁻¹ and corresponding ionization energies of 34–40 meV (e.g. Ref. [1]). After such heat treatments of Cz-Si, two paramagnetic centers are found

in (electron paramagnetic resonance) EPR as well. They were called NL8 for short annealing time of $t \approx 0.5$ h and NL10 for $t > 10$ h, respectively. The oxygen incorporation in the centers has been proven by electron nuclear double resonance (ENDOR) [2,3]. Several features (e.g. formation kinetics) suggest that the TDDs, found in FTIR, are identical with the NL8 defects, and that the STDs are identical with the NL10 centers [4].

The defects occurring after prolonged annealing ($t > 10$ h) can be divided into several families with a specific set of absorption lines for each of them in FTIR depending on the additional doping of the Si. Three families of STDs have been established so far: the STD(H) (incorporating hydrogen) [4], the STD(Al) (incorporating aluminum) [5], and the STD(X) (incorporation of nitrogen or lattice vacancies).

A new family of shallow thermal donors was found after hydrogenation and electron-irradiation of Cz-Si

*Corresponding author. Tel.: +49-5251-60-2740; fax: +49-5251-60-3216.

E-mail address: greulich-weber@physik.upb.de (S. Greulich-Weber).

and subsequent heat treatment in the range of 300–500°C [6,7]. The centers labeled D1–D3 show enhanced formation kinetics compared to the conventional STDs(H). In the irradiated Si:O:H samples, it is possible to choose the annealing conditions such that only one particular donor species dominates the spectra. This provides a better opportunity for structural studies of one particular species. We investigated the D1–D3 centers with FTIR and EPR spectroscopy and compared their properties with those of the STDs(H) and NL10(H) published previously. We show that the three types of shallow thermal donors (STD(H), NL10(H) and D1–D3) are “identical” and propose a structural model for them.

In FTIR investigations (resolution 0.5 cm^{-1}) it is found that the positions of some lines coincide in all the studied samples. Particularly, the lines due to D2 and D3 donors in irradiated samples are at the same positions as the corresponding lines in the spectrum of the non-irradiated sample (204.3 and 246.9 cm^{-1} for D2 and 198.3 and 241.2 cm^{-1} for D3) [6, 7]. These wave numbers are the same within experimental error as those cited in Ref. [4] for STD2(H) and STD3(H) centers confirming previous suggestions about the identity of the D2 and D3 donors and two centers of the STD(H) family [4,8].

Heat treatment at 350°C generates the D1 center with an isotropic EPR line at $g = 1.9987$. Heat treatment of the irradiated crystals at temperatures higher than 350°C results in a transformation of the D1–D2 centers. This leads to the transformation of the isotropic EPR signal to another one, the shape of which is characteristic for the defects with orthorhombic-I symmetry, C_{2v} point group. The orthorhombic-I symmetry of the D2 center was confirmed by detailed measurements in a K-band EPR spectrometer (25 GHz) and by electrical detection of EPR (EDEPR) at 72 GHz (V-band) with even better resolution. The principal values of the g -tensor are: $g_1||[001] = 1.99982(2)$, $g_2||[110] = 1.99722(2)$ and $g_3||[1\bar{1}0] = 1.99952(2)$. These values are close to those usually quoted for NL10 centers ($g_1 = 1.99959(2)$, $g_2 = 1.99747(2)$ and $g_3 = 1.99957(2)$) [2], but there is a small difference. The values of the D2 center indicate a slightly bigger anisotropy compared with the NL10 centers. The decrease in the concentration of the D2 centers and the appearance of the shallower D3 donors after annealing at 500°C leads to a more isotropic EPR with principal values of the g -tensor closer to those quoted for NL10 centers.

In the D1 EPR spectrum, when measured with increased integration time two satellite lines around the central line were detected. The ratio of the integrated area under the satellite lines to the total integrated area of all three lines is $4.7 \pm 0.2\%$. This value is in good agreement with the one expected for the hyperfine (hf) interaction with one ^{29}Si atom (natural abundance of ^{29}Si is 4.7%). From the angular dependence of the D1

Fig. 1. X-band ENDOR spectra of an electron-irradiated Si:O:H sample annealed at 350°C , measured at 7K with illumination of the sample with white light. Indicated is the position of the frequency of the free hydrogen nucleus calculated for a static magnetic field of $B = 352\text{ mT}$. Three spectra for the main crystallographic orientations are given.

satellite lines an isotropic hf interaction with $a = 58 \pm 1\text{ MHz}$ is derived. Microwave power-dependent measurements of the D1 satellite lines confirmed the correlation of the central D1 resonance line and the satellite lines. Similar ^{29}Si satellite lines with an intensity of $5.6 \pm 0.2\%$ were observed for the D2 center ($a = 70 \pm 1\text{ MHz}$).

A further Cz-Si sample was hydrogenated and finally annealed for 50 h which resulted in intense NL10(H) EPR. Also, for this sample, a hf splitting with one ^{29}Si ($a = 71 \pm 1\text{ MHz}$) is observed for the first time, the intensity of the EPR satellite lines being again 5.3%. It is noted that the splitting constant a for the D2 and NL10(H) centers is larger than that obtained for D1.

In order to reveal further, the atomic structure of the D(1-3)-species and to find out whether they also contain hydrogen, as the NL10(H) centers do, ENDOR measurements have been carried out. Fig. 1 shows ENDOR spectra in the frequency range of 14.8–15.2 MHz for a sample which had a strong D1 EPR signal. The observed ENDOR lines are positioned symmetrically around the Larmor frequency of free hydrogen showing ^1H incorporation into the D1 donor. The spectra are anisotropic upon rotation of the sample. Because of the strongly overlapping ENDOR lines their angular dependence could not be analyzed unambiguously. A satisfactory simulation of the spectra for various orientations could, however, be achieved when assuming triclinic symmetry for the ^1H hf tensor with the z -axis pointing almost into a $\langle 110 \rangle$ direction (only 3° off). There is only one hydrogen atom interacting.

Table 1
 ^1H hf interaction constants from ENDOR^a

	a (kHz)	b (kHz)	b' (kHz)	δ (°)	ψ (°)	φ (°)	$Q_{[001]}$ (kHz)
D1 (^1H)	∓ 88	± 40	± 20	90	45	26	—
D2 (^1H)	∓ 75	± 25	± 5	90	45	26	—
D1 (^2H)	∓ 13	± 6	± 3	90	45	26	± 64
NL10 (H)	84.6	15.2	14.8	75	30	55	—
	80.6	15.0	11.4	70	35	50	—

^a For D1(^1H) the isotropic constant a has an error of $\pm 10\%$; an error for b, b' is difficult to estimate. The error for D2 constants are somewhat larger ($a: \pm 20\%$). The quadrupole constant for D1(^2H) is probably $\pm 20\%$. The data for NL10(H) were adopted for comparison from Martynov et al. [11].

When replacing ^1H by deuterium the much smaller hf interaction of ^2H due to the much smaller nuclear g factor of ^2H could not be resolved, however, a quadrupole interaction could be determined showing that at the H/D site there is an electrical field gradient. The hf interaction parameters in their usual form used in ENDOR [11] are listed in Table 1. The absolute signs of the hf constants cannot be determined experimentally, only their relative signs which are opposite. The choice of a negative isotropic part a is explained below.

In the ENDOR spectrum of a sample containing D2 centers the lines are again placed symmetrically around the Larmor frequency of ^1H but with a reduced width of the pattern compared to that of the D1 centers indicating a smaller ^1H hf interaction, assuming again triclinic symmetry (Table 1).

It had been speculated that carbon is involved in the formation of the shallow donors STD(H) and D1–D3, respectively [4,9,10]. Although a sample enriched with ^{13}C to about $1 \times 10^{17} \text{ cm}^{-3}$ was used and sufficient D1 centers were produced to see the ^1H ENDOR spectra, no trace of a ^{13}C ENDOR line was found. Probably, there is such a low spin density at ^{13}C that the hf interactions were too small to be seen in ENDOR.

In order to obtain further evidence, high resolution FTIR measurements (resolution 0.05 cm^{-1}) were performed at 6 K with the sample enriched in ^{13}C . Isotope shifts of $\Delta E = -0.18 \text{ cm}^{-1}$ for the exchange of H by D and $\Delta E = -0.05 \text{ cm}^{-1}$ for the exchange of ^{12}C by ^{13}C , respectively, have been observed. The data being very small and at the limit of resolution. Thus, the incorporation of C into the D1 center has been demonstrated and confirms earlier speculations [4,9].

Do the shallow thermal donors STD(H), NL10(H) and D1–D3 all have different structures or are they the same defects which have been observed with different experimental methods initially and have therefore received different names? The coincidence of FTIR lines of D2 and D3 with those of STD(H)2,3 confirms earlier suggestions [4] that the D centers are identical with the STD(H) centers. The detection of hydrogen in the D centers by ENDOR supports this further. On the other

hand, the EPR data of NL10 defects and those of D centers with respect to symmetry and g -values are so similar, that the identification of NL10 in nominally undoped Si with the D centers is strongly suggested. Comparison of the hydrogen ENDOR spectrum published by Martynov et al. [12] with that for D1 and D2 shows a practical identical spectral shape and frequency extent. Also, the hf data are very similar, if one allows for the rather poor signal-to-noise ratio in Ref. [11] and the fact that a superposition of several species may have been measured since it was not as easily possible as here to generate one species separately as described above for the D centers. The hydrogen hf data of Ref. [12] adopted to our representation with a, b, b' are given in Table 1 for comparison. Martynov et al. also assumed triclinic symmetry, but did not find the opposite signs of a and b, b' . In view of the uncertainty of the precise analysis of the ENDOR angular dependence due to line overlaps and/or low signal intensity we think that H in NL10 and D centers has the same hf interactions (with slight variations from species to species in the family). Thus, STD(H), D1–D3 and NL10(H) are members of the same defect family. The fact that we have observed a prominent ^{29}Si hf interaction in EPR for both D and NL10(H) and the isotope shift on the ^{13}C enriched sample in high resolution FTIR strongly supports the shallow defect model calculated by Ewels et al. [10] and shown in Fig. 2: the shallow donors have a $(\text{C}-\text{H})_i-\text{O}_{2i}$ structure as defect core. The C_i atom is placed slightly above the $(1\bar{1}0)$ plane in which next to the Si lattice atoms the two O_i are located. The H_i is bonded to the C_i in the $[110]$ direction, which was found to almost coincide with the ^1H hf tensor orientation. The Si atom bonded to C_i in the $\langle 001 \rangle$ direction lacks bonding of its fourth electron. All constituents of the core of the model C, Si and H have been identified. The negative sign of the isotropic hf constant of ^1H is consistent with this model since it can be explained by exchange polarization of spin density in C_i [13], which in turn is caused by polarization from unpaired spin density in the adjacent Si. Assuming that the experimentally found spin density of 1.3×10^{-2} at ^{29}Si induces 1.3×10^{-3} spin

Fig. 2. Atomic model of the core structure of STD(H) on the basis of the calculations by Ewels et al. [10] and the results of this work.

density at the neighboring $^{13}\text{C}_i$, both the negative a value of ^1H and its b value can be quantitatively explained, using for a the known polarization effects of CH_3 radicals [13] (a full p_z orbital induces approximately -65 MHz at the proton) and for b the point dipole–dipole approximation using the CH -bond length of 1.2 \AA (for details see Ref. [14]).

The very low spin densities found are in qualitative agreement with the calculations of Ewels et al. [10] who due to a cluster calculation would overestimate the spin densities of these shallow and very extended defects. A direct comparison with their calculation is not possible since they give no explicit values in Ref. [10] (except for saying “very low”).

All the experimental results are consistent with the assignment of the D1, D2 and D3 centers to the STD(H)/NL10(H) family. The electronic properties of the D1 donor differ from those of the other STD(H) species (e.g. isotropic g factor versus, anisotropic ones of

NL10(H)), but it has the same core constituents and annealing behavior, in that D2 grows at the expense of D1. Thus, it appears that D1 is the first species of the STD(H) donor family and could be called STD(H)1.

P-type doping of hydrogenated amorphous silicon films with boron by reactive radio-frequency co-sputtering

Abstract

B has been successfully doped into the hydrogenated amorphous Si films without using explosive and/or toxic gases SiH_4 or B_2H_6 by reactive radio-frequency co-sputtering. The target used for co-sputtering was a composite target composed of a B-doped Si wafer and B chips attached on the Si wafer with silver powder bond. The maximum area fraction of B chips used was 0.11. Argon and hydrogen pressures were 5×10^{-3} and 5×10^{-4} Torr, respectively. Substrates were kept at 200°C or 250°C during sputtering. The maximum B concentration in the film obtained was $2 \times 10^{19} \text{ cm}^{-3}$ from secondary ion mass spectroscopy measurement. Films with resistivity of 10^4 – $10^5 \Omega \text{ cm}$ were obtained, which was low for the above acceptor concentration, compared with other group III impurities doping, indicating the high doping efficiency of B. A heterostructure, which was prepared by co-sputtering these B-doped films on an n-type crystalline Si, shows a good rectification characteristic. A small photovoltaic effect is also observed.

1. Introduction

The reactive radio-frequency (RF) co-sputtering has been widely used as a safe and inexpensive method for fabrication of doped hydrogenated amorphous silicon (a-Si:H) or silicon-carbon alloy (a-SiC:H) films without using any toxic or explosive gases. For the dopant used, Al has been investigated most extensively [1–5]. Saito et al. prepared a-SiC:H films doped with Ga [6] and Ti [7] by the co-sputtering method. In these group III acceptor impurities used, however, the concentration in the film reached 10% or more to obtain films with a low resistivity, e.g. $10^5 \Omega \text{ cm}$, so long as the substrate was kept around 200°C during deposition, where the amorphous Si crystallizes rarely. In some cases, the resistivity has not decreased to $10^5 \Omega \text{ cm}$, even if the impurity concentration exceeds 10% by far. This may be due to the low doping efficiency of these impurities. Incidentally, little has been reported about B

doping by this method, although B is the most easily doped to high concentration in the crystalline Si counterpart. In this study, it has been demonstrated that B was successfully doped and low-resistivity a-Si:H films were obtained with relatively low concentration of B by the reactive co-sputtering method. In Section 2, experimental details on the film preparation and the evaluation method are described. Experimental results are shown and discussed in Section 3.

2. Experimental

The sputtering targets used in this experiment are undoped Si crystal of 80 mm in diameter, B-doped p-type Si wafers and Si-B composite targets, where several $5 \times 5 \times 1 \text{ mm}^3$ and/or $10 \times 10 \times 2 \text{ mm}^3$ B chips were attached to p-type Si wafers with silver powder cement. Substrates for sputtered films are optical glasses for UV-Vis optical measurement and electrical measurement, ITO glasses and heavily B-doped p-type Si wafers for electrical measurement and high-resistivity p-type Si

wafers for IR measurement. To investigate pn diode characteristics, films were sputtered on n-type Si wafers. The substrates were kept at 200°C or 250°C during deposition for 1 h. The film was prepared in a conventional RF sputtering system operating at 13.56 MHz. The base pressure of the system was of the order of 1×10^{-6} Torr. Argon and hydrogen partial pressures used were mostly 5×10^{-3} and 5×10^{-4} Torr, respectively. A RF power of 2 W/cm² was used. The deposition rate of about 2 Å/s was obtained. The film thickness was measured by a stylus monitor (Sloan DEKTAK IIA). The H concentration was obtained from IR absorption, which was measured by a Shimadzu FTIR 4100 spectrophotometer. The B concentration in the film was determined by secondary ion mass spectroscopy (SIMS) using a CAMECA DES II. For electrical measurement, aluminum was evaporated for the electrode. Through the stencil mask, Al dots of 2 mm in diameter were evaporated on films deposited on ITO glasses and p⁺ Si wafers. The co-planar electrodes were also formed with about 0.2 and 0.5 mm gaps for films on glasses. Electrical properties were determined by a Keithley 2400 SourceMeter.

3. Results and discussion

In most glow-discharge prepared, B-doped a-Si:H films, the B concentration is expressed in terms of partial pressure ratio B₂H₆/SiH₄ during deposition [8]. In this work, to know the net B concentration directly, SIMS measurement was performed. In Table 1, configurations and the B concentrations for four different targets A, B, C and D are shown. In target A, where the most B chips were attached on the Si wafer, the area fraction reaches about 0.11. It was found that the B concentrations were reasonably constant through the film and were reproducible for each target. Therefore, several data are hereafter shown as a function of B concentrations as in Table 1. Fig. 1 shows micro-Raman spectra determined using Jasco NRS-2000 Raman microspectrometer for films prepared from target A at 200°C and 250°C. No

Table 1

Configurations of composite targets and B concentrations in the films determined by SIMS^a

Target	B chip area	Si target	B (SIMS) (cm ⁻³)
A	11%	p ⁺ Si	2×10^{19}
B	8%	p ⁺ Si	3×10^{18}
C		p ⁺ Si	2×10^{17}
D	p ⁺ Si 10%	p Si	2×10^{16}

^ap⁺ Si, B-doped 0.005–0.01 Ωcm Si wafer; p Si, B-doped 5 Ωcm Si wafer.

zone-center LO-TO phonon at 520 cm⁻¹, which is a sensitive signal for micro-crystalline Si formation, was observed even for the film prepared at 250°C, while the entire spectra are almost similar to those of the crystalline Si. Fig. 2 shows Si-H and Si-H₂ concentrations obtained from IR absorption bands at 2000 and 2100 cm⁻¹ for Si-monohydride and Si-dihydride stretching vibrations, respectively, using the method and the proportionality factors between the concentration and the optical densities determined by Langford et al. [9]. It is observed that, below 10^{19} cm⁻³ of B concentration, Si-H and Si-H₂ concentrations do not change significantly from those of undoped films, respectively, for both films prepared at 200°C and 250°C. Above 10^{19} cm⁻³, however, the hydrogen concentration decreases with B concentration, which is the same behavior as other impurities Al [5] or Ga [6],

Fig. 3. Optical band gap E_0 and $B^{1/2}$ (see the text) obtained from the Tauc plot of the UV-Vis optical data as a function of B concentration.

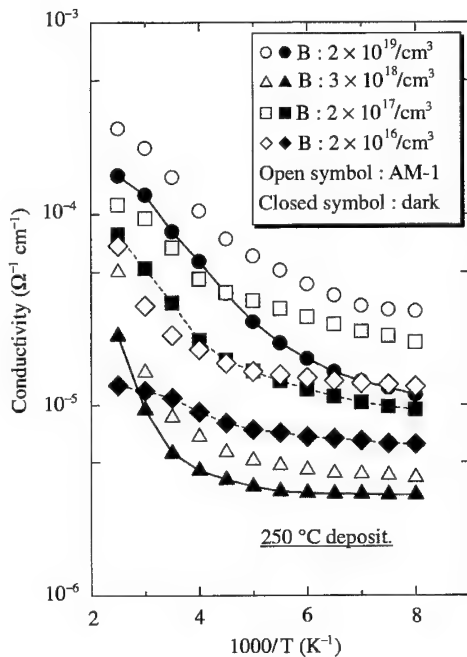

Fig. 4. Electrical conductivity as a function of temperature for B-doped a-Si:H films prepared at 250°C with and without AM-1 illumination.

although the transition concentration seems to depend on the impurity. In Fig. 3, the optical band gap E_0 and B factor are plotted against B concentration. Both quantities were obtained from Tauc plot of the optical data [10], $h\nu\alpha(v) = B(h\nu - E_0)^2$, where α is the absorption coefficient, with a simple assumption that two parabolic, conduction and valence bands are separated by the band gap E_0 [11]. Both E_0 and B have often been used as measures of disorder, decreasing with increasing

Fig. 5. I - V characteristics for B-doped p-type a-Si:H/n-type epitaxial Si at different temperatures.

disorder. The optical data with the absorption coefficient above about 10^4cm^{-1} have been used to avoid the interference effect. In Fig. 3, E_0 and $B^{1/2}$ obviously decrease, when B concentration exceeds 10^{18}cm^{-3} , which agrees with the data in a small B fraction region for hydrogenated Si-B alloy films prepared by the glow discharge deposition [8]. It is observed that, for films prepared both at 200°C and 250°C, both quantities at the middle B concentration are slightly higher than those of undoped films. In Fig. 4, the electrical conductivity is plotted as a function of temperature for B-doped a-Si:H films prepared at 250°C with and without AM-1 illumination. Although the order of the conductivity is not necessarily similar to that of B concentration for some films, the film for the target A has the maximum dark conductivity and the activation energy near room temperature is about 0.1 eV, which indicates that the Fermi level is close to the valence band edge. The photoconductivity, although small, is still observed for this film.

Finally, the diode data for B-doped a-Si:H/n-type crystalline Si junction will be presented. Fig. 5 shows an I - V characteristic determined at several temperatures for a diode in which a-Si:H film was sputtered using the target A in the Table 1 on the n-type (100) Si epitaxial wafer through a hole of about 1cm^2 of a stencil mask at 200°C. The electron concentration in the epilayer was $3 \times 10^{14}\text{cm}^{-3}$. For forward bias $V_f \leq 0.4\text{V}$, the current I was expressed as $I \sim \exp(eV_f/nkT)$ with the n value near 2, indicating that the current is dominated by the recombination current in the space-charge region of the junction. For $V_f > 0.4\text{V}$, however, no diffusion current component with $n = 1$ is observed, but the current seems to be limited by the high series resistance of the film. It was found that the I - V characteristics are particularly sensitive to the deposition temperature. The forward current is higher and the reverse current is

much smaller for the diode prepared at 250°C than that prepared at 200°C. The preliminary data showed that the short-circuit current of several tens $\mu\text{A}/\text{cm}^2$ was obtained for these diodes under AM-1 illumination.

4. Summary

It has been demonstrated that B-doped p-type a-Si:H films were prepared by the reactive RF co-sputtering using composite targets of B chips and Si wafers. No explosive and/or toxic gases, SiH_4 or B_2H_6 , were used. The B concentration in the film was directly measured by SIMS and could be controlled by the quantity of B chips and B concentration in the Si wafers in the composite target. The film of the maximum conductivity of about $5 \times 10^{-4} \text{Scm}^{-1}$ was obtained for the B concentration of $2 \times 10^{19} \text{cm}^{-3}$ and the Arrhenius plot near room temperature showed an activation energy of about 0.1 eV, indicating the Fermi level close to the valence band edge. The B-doped a-Si:H/n-type crystalline Si diode structure, which was prepared to confirm the p-type doping, showed a good rectification characteristic and a small photovoltaic effect was observed. These results show that B-doped a-Si:H films in this work contain high concentration of p-type carriers for relatively small B concentration, manifesting the high doping efficiency of sputtered B. Successful doping of B will pave the way for device fabrication by the sputtering

technique, although further optimization of, e.g., deposition condition is still necessary.

Abstract

Positron annihilation lifetime experiments have been performed for CZ-Si with B concentration ranging over 8.3×10^{17} – $2.5 \times 10^{20}/\text{cm}^3$ irradiated with 6 MeV electrons at room temperature. The mean lifetimes were hardly changed in the specimens with B below $8.0 \times 10^{18}/\text{cm}^3$, and increased in the specimen above $8.6 \times 10^{19}/\text{cm}^3$ by irradiation. No remarkable lifetime change with B concentration was obtained with the increase of electron fluence up to $5 \times 10^{15} \text{ e}/\text{cm}^2$, and the mean lifetimes of the specimens with B more than $8.6 \times 10^{19}/\text{cm}^3$ increased with electron fluences higher than $1 \times 10^{16} \text{ e}/\text{cm}^2$. It is concluded that complex defect clusters of $\text{B}_x\text{O}_y\text{V}_z$ are formed by electron irradiation, which have shorter positron lifetimes than the bulk. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Positron lifetime; Czochralski-grown silicon; Electron irradiation; Dopant boron

1. Introduction

In our previous study for B-doped CZ-Si specimens ($[\text{B}]: 2 \times 10^{15}/\text{cm}^3$) irradiated at room temperature with 1 MeV electrons with fluences between 10^{14} and $10^{17} \text{ e}/\text{cm}^2$ [1], it was found that the mean positron lifetime of irradiated Si becomes shorter than that of as-grown Si, which is due to an irradiation induced short lifetime component (approximately 100 ps). We have concluded that the short-lifetime component is associated with a singular defect, because a vacancy should have a longer lifetime than that of the bulk. It has been suggested that such defects are formed by dopant B atoms, interstitial oxygen atoms, and electron irradiation induced vacancies. The components with longer lifetimes than that of the bulk were also observed, and they were accounted to relate with thermal donors and divacancies.

In this paper, we report the positron lifetime study on dopant B concentration dependence on the defect

complex with shorter lifetime in order to clarify the role of B atoms.

2. Experimental procedure

B-doped CZ-Si wafers with various B concentrations ($[\text{B}]: 8.3 \times 10^{17}, 8.0 \times 10^{18}, 8.6 \times 10^{19}, 2.5 \times 10^{20}/\text{cm}^3$) with [100] orientation and a thickness of about 1 mm were prepared. The B concentration was determined by converting the resistivities with ASTM F723-88. The concentration of oxygen atoms amounted to $1.0 \times 10^{18}/\text{cm}^3$, which was obtained by infrared absorption measurements using the conversion factor IOC-88 [2].

Each specimen was irradiated with 6 MeV electrons at room temperature using a linear accelerator. The fluences ranged from 3×10^{14} to $1 \times 10^{17} \text{ e}/\text{cm}^2$. The flux rate of electrons was $6.3 \times 10^{12} \text{ e}/\text{s cm}^2$.

Positron annihilation lifetimes were measured at room temperature. A radioactive ^{22}Na source with an activity of 346 kBq covered by thin Ni foils were used. The spectra were obtained by the fast-fast coincidence system. The full-width at half maximum (FWHM) of

E-mail address: tamano@mtl.osakafu-u.ac.jp (T. Tamano).

the time resolution curves was 190 ps. Each lifetime spectrum was accumulated to 1×10^6 counts. The source components were calibrated using unirradiated FZ-Si specimens before and after each measurement. The lifetime spectra were analyzed and decomposed into two components with the RESOLUTION program [3].

3. Results and discussion

Fig. 1 shows the result of mean positron lifetime changes for the samples with different B concentrations as a function of electron irradiation doses. The lifetimes of the as-grown samples are roughly similar to each other; about 215 ps. The lifetime of the bulk Si has been reported to be 218 ps from experiments [4] and 215 ps from theoretical calculation [5]. The lifetimes of the samples below 8.0×10^{18} B-atoms/cm³ hardly change by irradiation. On the other hand, those above 8.6×10^{19} B-atoms/cm³ increase with irradiation. The amounts of Frenkel pairs formed by the electron irradiation are estimated to be 2.6×10^{17} /cm³ and 7.8×10^{14} /cm³ for the highest and the lowest fluence, respectively. Therefore, the positron lifetimes should be longer with the increasing irradiation dose. However, the irradiated samples with B below 8.0×10^{18} cm³ exhibit a somewhat different manner. It seems that a positron cannot be trapped by vacancies, in short, and the vacancies disappear by forming new types of defects. Boron concentration dependence of the electron irradiation is not observed below fluences of 1.0×10^{16} e/cm², while it is observed clearly above fluences of 1.0×10^{16} e/cm².

The positron lifetimes of two component analyses for the samples with different B concentrations are shown in Fig. 2 as a function of electron irradiation dose. The value of τ_1^{cal} is τ_1 calculated from τ_2 and I_2 of the two-state trapping model. The difference between τ_1^{cal} and τ_1 indicates that other types of defects coexist. The larger

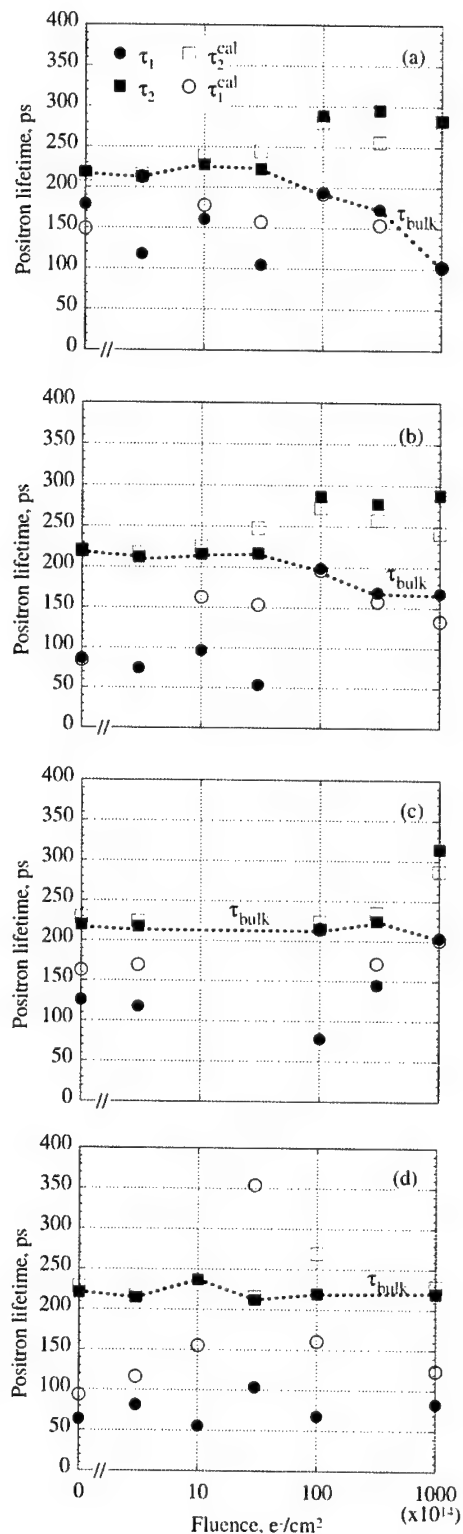

Fig. 2. Positron lifetimes for B-doped CZ-Si with different B concentration as a function of electron irradiation dose. (a) $[B] = 2.5 \times 10^{20}$ /cm³, (b) $[B] = 8.6 \times 10^{19}$ /cm³, (c) $[B] = 8.0 \times 10^{18}$ /cm³, and (d) $[B] = 8.3 \times 10^{17}$ /cm³.

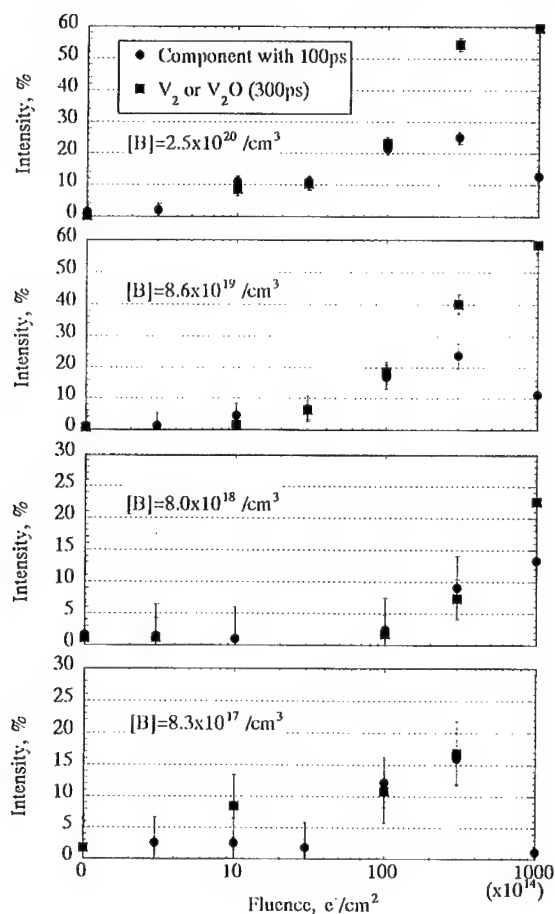

Fig. 3. Relative intensity change of each defect with electron irradiation dose.

the difference, the greater the other types of defects. A detailed discussion was already reported in a previous paper [6]. Fig. 2(d) shows the results for the positron lifetimes for the sample with $8.3 \times 10^{17} / \text{cm}^3$. Although the average lifetimes (τ_{av}) changes slightly at about 215 ps in a whole dose range, they could be decomposed into two components. In the ordinary two component analysis, τ_1 is usually thought to be the matrix. In the present case, however, we conclude that τ_2 is the matrix, and τ_1 is the defect, because τ_2^{cal} agrees with τ_2 , but not τ_1^{cal} with τ_1 . The average lifetime of the short-lifetime defects (τ_1) is about 80 ps. Dannefaer [5] suggested that the lifetime of positrons trapped by interstitial oxygen clusters (~ 100 ps) is shorter than that of positrons annihilated in the bulk (218 ps) in CZ-Si. Uedono et al. [8] have also reported that the lifetime of positrons trapped by the substitutional oxygen microclusters is 80 ps, and divacancies were also attributed to the formation of vacancy-oxygen microclusters in CZ-Si. The intensity of short-lifetime defect (I_1) is low, but the

short-lifetime defect appears in the whole irradiation range. The positron lifetime changes for the specimen with B of $8.0 \times 10^{18} / \text{cm}^3$ are presented in Fig. 2(c). The mean lifetime, τ_{av} does not change at about 215 ps, except for the lifetime at $1.0 \times 10^{17} \text{ e/cm}^2$. For each two-component analysis, it was checked whether τ_1 was the defect with shorter lifetime. As a result, we obtained both the bulk component and a short-lifetime component of about 100 ps with a defect intensity of about 10% with irradiation below $3.0 \times 10^{16} \text{ e/cm}^2$ as well as both the bulk and a long-lifetime component of 320 ps with an intensity of 18% with irradiation at $1.0 \times 10^{17} \text{ e/cm}^2$. The lifetime longer than that of the bulk agrees with that of a divacancy (V_2) or a complex with oxygen (V_2O) [5]. Fig. 2(b) shows the result for CZ-Si with 8.6×10^{19} B-atoms/ cm^3 . The analyses reveal that the short-lifetime defects are about 80 ps below $3.0 \times 10^{15} \text{ e/cm}^2$ and that the long-lifetime defects are about 290 ps above $1.0 \times 10^{16} \text{ e/cm}^2$. Fig. 2(a) for B-doped CZ-Si ($[B]: 2.5 \times 10^{20} / \text{cm}^3$) is similar to the specimen with B of $8.6 \times 10^{19} / \text{cm}^3$ in Fig. 2(b).

We obtained two types of defect lifetimes. One is a shorter lifetime defect about 100 ps, and the other is a longer lifetime defect about 300 ps like a V_2 type defect. Therefore, we try to fix these lifetimes, and compare each relative defect intensity as a function of electron dose as shown in Fig. 3. It should be noted that an ordinate scale of intensities becomes double between $8.0 \times 10^{18} / \text{cm}^3$ and $8.6 \times 10^{19} / \text{cm}^3$. It is found that for the samples with B above $8.6 \times 10^{19} / \text{cm}^3$, a fluence between 3×10^{15} and $1 \times 10^{16} \text{ e/cm}^2$ is a boundary range where the major defects change from the short-lifetime defects to the vacancy-type defects. The intensities of short-lifetime defects of all samples increase with fluence. Dependence of the short-lifetime defects on B concentrations was apparent. The intensity of short-lifetime defect becomes higher with increasing B concentration. It seems that B atoms accelerate the formation of short-lifetime defect and/or that B atoms are related to the short-lifetime defects.

The phenomena mentioned above can be explained as follows. Electron irradiation introduces a pair of vacancy (V) and a self-interstitial atom (Si_i) called a Frenkel pair. As for diffusion of B, Cowern et al. [9] proposed a kick-out mechanism that Si_i kicks substitutional B (B_s) out to the interstitial regions, and suggested that a B_s - Si_i pair is stable and interstitial B (B_i) is metastable. Therefore, it is thought that electron irradiation induces a kick-out mechanism, and then B_i diffuses and meets interstitial O (O_i). It is expected that B_i and O_i interact with each other and create a complex. The DLTS measurements by Khan et al. [10] have also suggested that the V-O-B or B_i - O_i appeared in CZ-Si. However, since B_i is metastable, a reverse kick-out mechanism may take place and a formation of B_s - O_i pair is certainly expected. We may consider excess B

atoms that are bound to the remaining V, but V_2B is known to be unstable at room temperature. Therefore, it is suggested that V remains independent. As the B concentration becomes high, the rate of kick-out mechanism will be large, resulting in the increase in concentration of the defect complex. A high dose of electron irradiation will create such a complex, but positron will not be trapped by it, because the defect complex with a shallow trapping site will be masked by vacancy type defects. The cause of disappearance of V-type defects for lower B concentration samples is considered by the supersaturated interstitial oxygen atoms that are residual without being perfectly relaxed by vacancies introduced by the present low electron fluences. It is accounted that an interstitial oxygen atom distorts the Si lattice and changes atomic spacings, because of a bigger covalent bonding radius than that of the Si bulk. Since interstitial oxygen atoms induce dilatational strains in the Si lattice, the formation of complex defects with vacancies is highly expected. On the other hand, the covalent bonding radius of B atoms is smaller than that of Si, because B atoms are located at substitutional lattice sites, and the lattice will be shrunk around B atoms. Hakala et al. have reported from ab-initio calculation [7] that the substitutional B atom relaxes the nearest-neighbor silicon atoms inwards by $\sim 12\%$ of the bulk bond length. Therefore, B atoms work partly the same as the vacancies. Since it is thought that interstitial O atoms are combined with B substitutional atoms, it is safely concluded that vacancies remain at free conditions like V_2 or V_2B in the samples above $8.6 \times 10^{19}/\text{cm}^3$. On the other hand, in the samples below $8.0 \times 10^{18}/\text{cm}^3$, the vacancies are trapped by the interstitial O atoms, because the number of B atoms is smaller. Accordingly, from the view of the short-lifetime defects, they were more relaxed by B atoms in the specimen with higher B concentrations and irradiation-induced vacancies than that with lower B concentration and the same number of vacancies.

The present study clearly indicates that the induced short-lifetime components are defect complexes with impure interstitial oxygen atoms, vacancies and doped B atoms. From a viewpoint of positron trapping, lifetimes shorter than that of the bulk result from both the smaller

Coulomb potential from the nucleus and the larger electron densities than those of the bulk. The proposed short-lifetime model is satisfied by the conditions, because both oxygen and B nuclei with smaller positive charges exhibit Coulomb repulsive forces smaller than that of the Si nucleus. Accordingly, positrons are easily trapped by such complexes, resulting in annihilation with electrons around oxygen and boron atoms at earlier times.

4. Conclusions

The short-lifetime component is responsible for a complex defect with impure interstitial oxygen atoms, doped B atoms and vacancies. It was concluded from the positron annihilation experiments that B-doped CZ-Si contains the complex $B_xO_yV_z$, which have a shorter positron lifetime than that of the bulk. It is found that B is related with the short-lifetime defects, and it accelerates the formation of short lifetime complexes.

Interstitial carbon reactions in n-Si induced by high-energy proton irradiation

K. Kono*, H. Amekura, N. Kishimoto

National Institute for Materials Science, Nanomaterials Laboratory, 3-13 Sakura, Tsukuba, Ibaraki, 305-0003, Japan

Abstract

The effect of oxygen on the interstitial carbon reactions in n-Si created by high-energy proton irradiation was studied by an in situ DLTS measurement system. The suppression of Watkin's replacement reaction by trapping of interstitial silicon was studied. The release of the interstitial silicon from interstitial oxygen complex and the following interstitial carbon was studied by in situ DLTS measurement. Also, the effects of interstitial carbon reactions on CCD performance is discussed as an example of application. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Defects; Interstitial; Oxygen

1. Introduction

Vacancies and self-interstitials in Si, induced by high-energy proton irradiation, react with impurities and form defect complexes, which produce undesirable deep levels and affect device operation. Most of the past studies on interstitial type defects focus on reactions after interstitial carbon (C_i) is created from substitutional carbon (C_s), replaced by self-interstitial (I) [1]. The reaction is called Watkin's replacement reaction and is known to take place as low as 4.2 K [2]. The C_i reacts with impurities and forms defect complexes. Since I is trapped by O at low temperature, the production of C_i and the defect complexes is suppressed by the presence of O [1,3]. In order to understand the whole damage processes, it is important to evaluate the dynamic reactions, including Watkin's replacement reaction. We studied the interstitial reactions using an in situ DLTS system integrated in the cyclotron.

We also briefly discuss the application of the study of the interstitial carbon reactions on actual device performance. The discussion is based on the cooled CCD onboard the NASA's Chandra X-ray observatory [4]. Its charge transfer channel was damaged by protons

during the passage of the radiation belts around the earth. We show the importance of understanding the whole process.

2. Experimental

The samples were cut from commercially available n-Si wafers. Either CZ wafers whose resistivity was $\sim 10 \Omega \text{cm}$ (phosphorus concentration: $7 \times 10^{14} \text{cm}^{-3}$) or FZ wafer whose resistivity was in the range $3\text{--}5 \Omega \text{cm}$ (phosphorus concentration: $3 \times 10^{15} \text{cm}^{-3}$) was used. The oxygen concentration of CZ samples was determined to be $2 \times 10^{18} \text{cm}^{-3}$ by atomic absorption analysis. By comparing the FT-IR signal with FZ and CZ sample the oxygen concentration of the FZ silicon was determined to be more than 10 times lower than that of CZ silicon. The carbon concentration in the wafer was determined by chemical analysis to be $3 \times 10^{17} \text{cm}^{-3}$ for CZ and $5 \times 10^{17} \text{cm}^{-3}$ for FZ sample. Samples were cut into rectangular shape and gold was vacuum evaporated on the front surface to form a Schottky diode. An ohmic contact was formed on the other surface.

Irradiation was conducted using the National Institute for Materials Science cyclotron. A proton beam of 17 MeV was used to irradiate the samples. A closed cycle

refrigerator was used to cool the sample down to 50 K. In situ DLTS measurement was conducted right after irradiation or after annealing. The projectile range of the 17 MeV proton was calculated to be 1.7 mm according to the SRIM calculation, which insures the absence of hydrogen remains in the sample and the uniformity of the defects concentration over the depth range [5].

The beam current density of the proton was maintained at about 30 nA cm^{-2} and the total fluence was varied from 1.0×10^{13} to $7.2 \times 10^{13} \text{ ions cm}^{-2}$. The irradiation was conducted between 200 and 300 K.

In order to avoid the annealing during the temperature scan of DLTS, the upper limit of the scan was restricted to the irradiation temperature. In situ measurement was used to study the kinetic process of the defect reactions without annealing.

3. Experimental results

A typical DLTS result of the FZ silicon is shown in Fig. 1. The sample was irradiated at 200 K. Without annealing, the C_1 peak around 70 K (0.12 eV) can be clearly seen. At this temperature, the diffusion of C_1 and further reactions are impossible since the migration enthalpy is 0.84 eV [6]. Isochronal annealing of 30 min was conducted by increasing the temperature up to 400 K. An annealing at 350 K diffuses the C_1 and creates the C_1C_5 structure which overlaps VO at 98 K (0.18 eV).

Similarly the low temperature irradiation results of CZ silicon are shown in Fig. 2. After irradiation at 200 K, isothermal annealing was conducted since previous experiments showed that a lot of defect reactions can be observed at this temperature [7]. No C_1 -related signal is detected right after irradiation. This is due to the trapping of I by O [1,3]. The trapping was previously studied optically [3]. We have used in situ measurement

Fig. 1. n-type FZ silicon was irradiated at 200 K followed by isochronal annealing for 30 min. The peak at 70 K corresponds to C_1 . As the peak at 98 K increases, the peak at 70 K decreases.

Fig. 2. n-type CZ silicon was irradiated at 200 K followed by isothermal annealing at 250 K. No interstitial carbon related peak is observed without annealing.

to prove the phenomena. The isothermal annealing was conducted to study the reaction with the slow dissociation of IO complex. The released I immediately replaces the C_5 and C_1 is created. The diffusion of C_1 at 250 K is still very limited. The C_1 reacts with C_5 and forms C_1C_5 which overlaps VO peak at 98 K (0.16 eV). However, during the isothermal annealing at 250 K, C_1 dissolves again and another level at 80 K (0.16 eV) is created [7].

4. Discussion

The result of isochronal annealing of the FZ silicon can be interpreted as follows. The diffusion of the C_1 becomes more active as temperature increases and C_1C_5 is formed which has a peak overlapping VO.

In the case of CZ silicon, I created during anneal is trapped by oxygen and no C_1 -related signal is detected. Only with annealing at 250 K C_1 is created. This is the clear indication of the trapping of the I by oxygen and the resulting suppression of the generation of the C_1 . After 30 min of annealing C_1C_5 at 98 K (0.18 eV) and C_1 at 70 K (0.12 eV) are observed. Continuous isothermal annealing dissolves C_1C_5 and increases C_1 (0.12 eV) and another structure at 80 K (0.16 eV). The difference in the reactions in FZ and CZ silicon is probably caused by the difference in phosphorus concentration which affects the charge states of the deep centers and the stability. The lower phosphorus concentration in CZ causes lower Fermi level and causes the states to remain neutral. The above charge state effect is considered to play an important role in the difference of the reactions. The detailed effects are still under investigation.

As an example to show the practical application of the knowledge of C_1 reactions, we analyze the case of the CCD. Similar analysis was done on radiation damage of

the NASA's Chandra X-ray observatory [4]. It has a CCD cooled around 150 K to detect X-rays. The radiation induced deep levels in the charge transfer channel caused the deterioration of the energy resolution by trapping of electrons. The maximum temperature its circuit could endure was 50°C.

In order to characterize the effect of the radiation defects on CCD performance, the value of CTI is found to be most important. The CTI stands for the charge transfer inefficiency and a larger value means more loss of charge during the transfer. Since the charge transfer is done repeatedly inside CCD, a slight increase in CTI can result in a great loss in electrons and can cause uncertainty in received light energy. The relationship between the capture by deep centers and CTI is [8]

$$\text{CTI} = \left(\frac{V_s}{N_s} N_t \right) \left(\exp \left(-\frac{T_t}{\tau_s} \right) \left(1 - \exp \left(-\frac{T_s}{\tau_s} \right) \right) \right),$$

where V_s is the volume of the signal charge packets, N_s is the number of electrons in the charge packets, N_t is the trap (deep centers) density, T_t is the transfer time in which carrier emission can occur, τ_t is the trap emission time constant, and T_s is the average time between charge packets. The emission time can be written as follows:

$$\tau_s = \frac{g}{\sigma_n v_t N_c} \exp \left(\frac{E_t}{kT} \right),$$

where g is the degeneracy of the trap level, σ_n is the capture cross section of the trap, v_t is the electron thermal velocity, N_c is the conduction band density of states and E_t is the energy level of the trap.

We have plotted the effects of radiation induced defects in Fig. 3. We analyze the effects of the change of structures in FZ and CZ silicon as an example.¹ Assume that FZ-Si is used for the manufacturing of the CCD. Since the CCD is maintained at 150 K, we only have C_1 and the vacancy type defects. The exact effect of CTI is not plotted in Fig. 3 since an accurate capture cross section was not available, but its energy level of 0.12 eV is too shallow to do any serious harm at 150 K. On the other hand C_1C_s produced by annealing is quite harmful as can be seen from Fig. 3. Therefore, in the case of FZ-Si annealing at room temperature will only damage the performance. Even if we assume that CZ-Si is used, the same conclusion is reached. At 150 K, no C_1 will be created because I created will be trapped by oxygen and the resulting IO does not capture the electrons. Also there is no decrease of vacancy related defects. This analysis shows why the annealing attempt of recovering the CCD performance failed and stresses the importance

Fig. 3. The CTI of the maximum irradiation-induced electron capturing defects. To calculate CTI $v_t N_c = 1.6 \times 10^{21} \text{ T}^{2.5} \text{ s}^{-1} \text{ cm}^{-2}$ is assumed. The capture cross sections used are as follows: VO(0.17 eV) $1 \times 10^{-14} \text{ cm}^{-2}$, $V_2(0.23)$ 4×10^{-16} , PV(0.44), $C_1C_s(0.17)$ 4×10^{-17} , CP(0.30) 1×10^{-17} , CP(0.29) 3×10^{-17} , CP(0.23) 4×10^{-16} , CP(0.21) 2×10^{-16} .

of the understanding the reactions of interstitial type defects.

5. Conclusion

The trapping of the silicon interstitial and the resulting suppression of Watkin's replacement mechanism was clearly shown by in situ DLTS measurement. The dynamic reactions of the interstitial carbon below room temperature were studied. The possibility of controlling the interstitial defects reactions by the oxygen concentration was clearly shown. The effect of the change of the C_1 -related defects on cooled CCD performance is discussed as an important example in studying the whole process of the interstitial defects.

On the correlation character between the structure perfection and electroluminescent properties of terbium doped silicon monoxide films

V.S. Khomchenko, L.I. Berejinskij, M.V. Sopinsky*

Institute of Semiconductor Physics, National Academy of Sciences of Ukraine, 45, Prospect Nauky, 03028 Kyiv, Ukraine

Abstract

The present work is devoted to the investigation of structural changes accompanying the appearance of green and blue electroluminescence in thermally deposited $\text{SiO}_x:\text{Tb}$ ($x \sim 1$) films as a result of high-temperature processing. The non-destructive optical methods, specifically, measuring transmission spectra in ultraviolet, visible, near and far IR area, and multiangle ellipsometry have been used for such a research. Analysis of the obtained experimental results allows to conclude that the annealing-stimulated structural transformations in a matrix of terbium doped silicon monoxide films occur at both microstructural and macrostructural levels and have an essential and complex influence on the film radiative performances. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Microstructure; Macrostructure; Silicon monoxide; Electroluminescence

1. Introduction

Silicon monoxide films (SiO_x , $x \sim 1$) have attracted the attention of many researchers. Their physical properties are acceptable for the development of luminescent layers for the light-emitting structures. The ZnS films are widely used for this purpose. The SiO_x films, however, do not degrade in the presence of the atmospheric water vapour. Besides, unlike the ZnS films, they have a lower refraction index, allowing to substantially increase the radiation from thin-film electroluminescent structures (TFELS).

Recently [1], the new TFELS with terbium doped silicon monoxide emitting layer have been developed, in which for the first time the colour of the electroluminescence (EL) could be changed from green to blue. The EL colour change has been achieved by high-temperature processing. The present work is devoted to the

investigation of structural changes occurring in a matrix of thermally deposited $\text{SiO}_x:\text{Tb}$ ($x \sim 1$) films as a result of high-temperature processing.

2. Technique and samples

$\text{SiO}_x:\text{Tb}$ films with thickness of about 0.5 μm were obtained by simultaneous vacuum deposition of SiO_x and TbF_3 vapours volatilized from separate sources on pure silicon and sapphire substrates heated to the temperature of 200°C. The residual pressure was 0.6 mPa and the deposition rate was $\sim 1 \text{ nm/s}$. The film thickness was measured with an interferometer. The Tb concentration in films was 1.5 at%. The EL spectra were obtained using films deposited on the BaTiO_3 ceramic substrate.

The high-temperature treatment of films was done in air within 600–1000°C range of annealing temperature (T_a) for 1 h with the subsequent slow cooling. Without this, $\text{SiO}_x:\text{Tb}$ films did not display any photo- or electro-luminescence. The IR- and the visible-transmission spectra were taken using Perkin–Elmer-599B and

E-mail address: sopinsk@class.semicond.kiev.ua (M.V. Sopinsky).

SPECORD UV VIS spectrophotometers. Ellipsometrical measurements were made with LEF-3M ellipsometer ($\lambda = 632.8$ nm).

3. Results and discussion

The EL spectra of $\text{SiO}_x:\text{Tb}$ films annealed at various T_a are shown in Fig. 1. It can be observed that annealing at 800°C results in the common EL of terbium with a maximum at $\lambda = 540$ nm. It corresponds to $^5\text{D}_4\text{--}^7\text{F}_5$ emissive transition [2]. Such an EL was earlier observed in $\text{SiO}_x:\text{Tb}$ films annealed at 600°C [3]. The rise of annealing temperature to 800°C considerably increases its intensity. However, annealing at higher T_a changes the EL spectrum a lot: the intensity of bands in blue area increases by about 2 orders of magnitude, and the dark blue EL becomes dominant. The intense band closer to $\lambda = 385$ nm ($^5\text{D}_3\text{--}^7\text{F}_6$) is observed in EL spectrum. The structure of Tb ion energy levels is well known [2], and the observed EL maxima matches it well. Therefore, the apparent changes in EL spectrum are tied to the violation of selection rules and probabilities of the relevant transitions of Tb^{3+} ion, which is the consequence of high-temperature annealing. This can be caused by the structural changes in an amorphous SiO_x network, or by the structural change of a cluster surrounding the impurity ion.

The optical constants (n : refraction index, κ : absorption index) and film thickness (d) were determined with

the help of the computer program described in [4,5]. The model of homogeneous and isotropic substrate and film was used. The following n values are obtained:

T_a ($^\circ\text{C}$)	200	600	800	1000
n	1.84	1.89	1.84	1.745

The $T(\lambda)$ transmission spectra of single-stage annealed $\text{SiO}_x:\text{Tb}$ films on sapphire substrates in the visible range of a spectrum are shown in Fig. 2. The behaviour of transmission spectra with an increase of annealing temperature is non-monotonous. In the interval of $T_a = 200\text{--}800^\circ\text{C}$, the long-wave shift of absorption edge increases with increase of T_a . However, further increase of T_a causes the short-wave shift of transmission spectrum of such films relative to the $T(\lambda)$ spectrum at $T_a = 800^\circ\text{C}$: the higher the T_a , the greater the shift. As a result, the film annealed at 1000°C becomes somewhat more transparent in the visible range of the spectrum than the initial as-deposited $\text{SiO}_x:\text{Tb}$ films.

Fig. 3 shows the $\text{SiO}_x:\text{Tb}$ IR-absorption spectra for the annealed film at varying temperatures. For the as-deposited film, the wide high-intensity absorption band with a maximum (ν_m) closer to 1000 cm^{-1} is observed. The shift of this band towards higher frequencies ($\nu_m = 1055\text{ cm}^{-1}$) occurring at just 600°C as well as some narrowing of it were observed. The annealing at 800°C

Fig. 1. The EL spectra of $\text{SiO}_x:\text{Tb}$ films annealed at 800°C (1) and 1000°C (2).

Fig. 2. Transmission spectra of $\text{SiO}_x:\text{Tb}$ films on sapphire substrate: as-deposited (1) and annealed at $T_a = 600^\circ\text{C}$ (2); 800°C (3); 1000°C (4).

Fig. 3. IR-absorption spectra of as-deposited (1) and annealed in air (2,3) $\text{SiO}_x:\text{Tb}$ films. $T_a = 800^\circ\text{C}$ (2) and 1000°C (3).

causes further band shift towards higher frequencies ($\nu_m = 1085\text{ cm}^{-1}$), along with a further increase and narrowing. The extended shoulder appears on its high-frequency part. These are the typical features of the fused silica IR-spectrum. Also, besides this, there are absorption bands closer to 460 and 800 cm^{-1} , specific for the network of glassy SiO_2 . Annealing at 1000°C leads to an even more prominent display of SiO_2 spectra features in the absorption spectrum of annealed film.

The change of n at $\lambda = 632.8\text{ nm}$ located at the absorption edge (see Fig. 2) can be caused by the shift of the optical absorption edge, and accordingly, by a shift of dispersion curve $n(\lambda)$ [6]. In turn, the shift of optical absorption edge is caused by the change of microstructure of a film, i.e., in the case of amorphous films, change of statistical parameters describing the short- and middle-range order in them. On the other hand, the change in n can be caused as well by the film macrostructure change, such as its texture, degree of macroscopic compactness caused by occurrence or disappearance of pores, hollows, flaws (cracks), etc. [7].

The values of x in $\text{SiO}_x:\text{Tb}$ films were estimated using the obtained n values as well as using $n(x)$ dependences for thermally evaporated SiO_x films [8] and are given in Table 1. The x_E for as-deposited film is 1.17, and it decreases to $\sim 0.05\text{--}0.1$ at $T_a = 600\text{--}700^\circ\text{C}$. Apparently, the film structure changes are caused by secondary (after the deposition) redistribution of positions and bonds among the particles, and partial decomposition of random-bonding network which is accompanied by a

Table 1

Stoichiometry indexes for $\text{SiO}_x:\text{Tb}$ calculated from ellipsometrically measured refraction index (x_E) and from the IR-absorption peak position (x_{IR})

T_a	x_E	x_{IR}	x_{IR}/x_E
Deposition	1.17	1.18	0.01
600°C	1.12	1.63	0.51
800°C	1.17	1.96	0.79
1000°C	1.28	1.96	0.68

desorption of oxygen. At $T_a \sim 800^\circ\text{C}$, the rise of x becomes observable (caused, apparently, by further oxidation process). This oxidation intensifies at $T_a = 1000^\circ\text{C}$. However, there is no complete film oxidation for SiO_2 . This is also confirmed by the data on the optical absorption edge for these films (Fig. 2).

It has been shown in Refs. [9,10] that the microstructure of SiO_x films obtained by thermal evaporation of silicon monoxide corresponds to the random bonding model (RBM). Within the framework of the RBM model [11], the SiO_x film represents the single-phase statistical intermixture of $\text{Si}-(\text{Si}_i\text{O}_{4-i})$ ($0 < i < 4$) tetrahedra bound through bridging oxygen. In these works, the empirical $\nu_m(x)$ dependence for such films has also been determined. We have utilized these dependences to determine the oxygen content in our films. The values obtained are given in Table 1. For the as-deposited $\text{SiO}_x:\text{Tb}$ films, the value thus obtained is $x_{IR} = 1.18$. It conforms very well to $x_E = 1.17$. However, for the high-temperature annealed films, such conformity of x_E and x_{IR} values has not been observed. Thus, one can conclude that the microstructure of $\text{SiO}_x:\text{Tb}$ films annealed at high temperatures cannot be described by the RBM. Such films have an increased content of areas with SiO_2 -like stoichiometry (compared to the statistics of random bonding). However, at $T_a > 800^\circ\text{C}$ the improvement in the film homogeneity is observed. Apparently, such an ordering of film structure improves the carrier heating conditions in the electric field.

So, it has been shown that film structure changes and that light-emitting characteristics are non-monotonic when the annealing temperature rises. The occurrence of green EL ($T_a = 600\text{--}800^\circ\text{C}$) is accompanied by a structural reorganization of a matrix resulting in partial decomposition of deposited films. As a result, these films represent an intermixture of several phases— Si , SiO_x and SiO_2 . Films displaying blue EL ($T_a \sim 1000^\circ\text{C}$), have a comparatively higher content of oxygen, better compactness, and macroscopic homogeneity compared with both as-deposited and annealed at $600\text{--}800^\circ\text{C}$ films.

The control mechanism of the impurity agglomeration triggered by ion impacts

S.T. Nakagawa*

Simulation Science Center, Okayama University of Science, 1-1 Ridai-cho, Okayama 700-0005, Japan

Abstract

We have studied the agglomeration mechanism of impurity B ions due to a high-dose ion implantation into Si, making use of a defect analysis performed with a molecular dynamic simulation. Beyond a threshold level of impurity concentration, ion irradiation drastically changes the spatial distribution of crystal atoms, which promotes the agglomeration significantly. The lattice reaction for the ion impact was often synergistic and depended strongly on the temperature of the host target, even with the same condition of irradiation energy. At a temperature of 100 K, the agglomeration once increased then decreased, because dissociation took it over. Above 200 K, however, the agglomeration progressed with ion impact. Such an analysis was possible by means of *pixel mapping* that showed the long-range interactions between atoms in a crystal. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The impurity agglomeration is often observed due to high-dose (Φ) ion implantation, when the concentration exceeds a certain level. For example, the critical concentration is 1–2 at% for cases of Au, Ag, B, in Si [1]. We have looked at an experiment [2] of B implantation into Si(100) with an energy of 35 keV with $\Phi = 3 \times 10^{16} - 1 \times 10^{17} \text{ cm}^{-2}$ at RT, which confirmed the formation of B_{12} clusters. A qualitative explanation based on the formation enthalpy failed to explain the agglomeration of impurity ions with a few %, because impurity ions are separated from each other farther than 10 Å in average.

When a crystal is heavily irradiated, accumulated defects may cause a synergistic reaction of a phase transition or a new event [3]. It strongly depends on the temperature of the host crystal, T_h , and the irradiation energy, E , as well as amorphization of a crystal, the impurity agglomeration is a typical case of it. In this case

of B implantation into Si, the homogenous amorphization occurs at $T_h < 200\text{--}300 \text{ K}$ [4] and $\Phi > 10^{15} \text{ cm}^{-2}$ [5]. Since we are looking at a case of $T_h = \text{RT}$ and $\Phi \leq 10^{17} \text{ cm}^{-2}$ [2], the agglomeration mechanism should closely relate to amorphization.

Making use of molecular dynamics (MD) we proved that ion irradiation was indispensable for agglomeration. We reproduced the B agglomeration, up to B_{11} clusters, and also confirmed that the critical concentration for B clustering was 2% as was measured [1]. This concentration demanded us to solve the mechanism by considering long-range interactions between atoms. Therefore, we proposed a new analysis of pixel mapping (PM) that could reveal the cooperative behavior of atoms in a crystal [6], for studying the correlation between the lattice reaction and the agglomeration.

2. Method: parallel analyses during the course of MD simulation

In order to depict the lattice reaction for ion bombardment, we took T_h from 100 to 400 K. The

E-mail address: stnak@dap.ous.ac.jp (S.T. Nakagawa).

reason for the higher end of 400 K was being afraid of an irradiation heating, whereas the lower end was to suppress the thermal effect as much as possible. The elevated T_h was supposed to be less than 50°, while the nominal value was $T_h = RT$. The average energy of the projectiles entering the MD-box was 4.5 keV [1]. When we bombarded Si crystal whose initial concentration of impurity, C_0 , was a few % with energetic ions of $1 \text{ keV} \leq E \leq 5 \text{ keV}$, projectiles caused agglomeration but they themselves run through the MD-box [1]. Therefore, in the present calculation we analyze the intermediate processes resulting in the agglomeration, with the conditions $E_{\text{max}} = 5 \text{ keV}$ and $C_0 = 3\%$. The following quantities are calculated at each moment when the system is thermalized after each ion impact. The longest cooling time was 2 ps.

Three types of radial distribution functions, $g(r)$, were calculated, where r stands for the internuclear distance. The $g(r)$ for the Si–Si correlation shows the entire imperfection of the host crystal, that for the B–Si the stability of B atoms accommodated in a Si crystal, and that of B–B the progress of the agglomeration. We take the longest distance r for $g(r)$ 5 Å for all cases because of the cut-off lengths of the potentials adopted.

If agglomeration had started, the mesoscopic view of the intermediate process following ion irradiation is obtained from the size distribution of B_m clusters that is made of m B atoms. The index of agglomeration, $k(n)$, is the fraction of agglomerated B atoms in the MD-box after the n th impact:

$$k(n) = \frac{\sum_{m=2} m B_m(n)}{\sum_{m=1} m B_m(n)}. \quad (1)$$

We proposed a new method of PM, in order to analyze the cooperative change relating to defects in a crystal, which is parallelly done with the MD. It identifies atoms whether they are in the stable, metastable, or unstable sites. The detailed algebra is explained elsewhere [6]. The definition of $N_i(n)$ is the occupied fraction of the i th kind of pixel after the n th ion impact. When a Si crystal is perfect, a Si atom is placed in a stable pixel (1) or (2), which gives us $N_{(1)}(0) = N_{(2)}(0) = 0.5$. A metastable pixel {H} includes one “H-site” at its center, which is mathematically and physically paired with a (1) pixel. The similar relation stands between (2) and {T}. The ensemble of pixels (1) and (2) forms a real FCC structure, respectively, while that of the {H} or {T} forms a *virtual* one.

All the residual pixels offer unstable sites for the target atoms. The geometric relation of $\langle 1' \rangle$ with (1) is as follows. According to normal crystallography, an ensemble of the stable sites of a diamond crystal forms a honeycomb lattice on a (111) plane. Therefore, the centers of pixels (1) form such a honeycomb, whereas those of the unstable pixels $\langle 1' \rangle$ form a smaller honeycomb in the same plane, which is exactly half the

size. All other kinds of unstable pixels have the same relation to their own *parent lattice*. The superior difference of the PM to other analyses is to show the long-range information from an ensemble of atoms that locate at physically equivalent positions in a periodic crystal.

3. Results

The calculations were done with conditions of $E_{\text{max}} = 5 \text{ keV}$ and $C_0 = 3\%$. Before starting ion impact, we leave the system until the thermalization has been established for 2–3 ps, at longest. With this process, the initial state was $N_{(1)}(0) = N_{(2)}(0) = 0.5$ for Si atoms. The B atoms preferably occupied the metastable {T} or {H} sites, not substitutional ones. Here, the total number of the Si atoms is 4096 for $T_h = 400 \text{ K}$ and 1728 for other cases. The number of ion impacts is determined by a Monte-Carlo calculation. The experimental condition of $\Phi = 10^{17} \text{ cm}^{-2}$ corresponds to about 150 impacts onto an MD-box if it contains 1728 Si atoms. Then we took 200 projectiles at the maximum.

3.1. The lattice response described by $N_i(n)$ superior to $g(r)$

The three kinds of $g(r)$ were calculated during the course of the ion impacts at $T_h = 400 \text{ K}$. Each profile changed monotonously to its random one. Once a random state was achieved, the change looked irreversible. In the case of $T_h = 100 \text{ K}$, after a drastic disappearance of the Si atoms located at the stable states (1, 2), all the pixels were soon occupied with even probability, i.e., a random state was achieved [6]. On the other hand, no drastic change appeared in the case of $T_h = 400 \text{ K}$. Moreover, crystalline atoms react cooperatively in a more complicated way as is shown in Fig. 1. Fig. 1a shows the fraction of Si atoms accommodated at the stable (1, 2) and the metastable {T, H} pixels. Fig. 1b shows those of the unstable pixels $\langle 2', H' \rangle$ and $\langle 1', T' \rangle$. In Fig. 1c, the case of the B atoms is shown. The B atoms were accommodated at the {T, H} pixels, then (1, 2) pixels, as if they exchange the sites with the Si atoms.

The remarkable differences of the lattice reaction at T_h higher than 100 K are: (1) Pronounced peaks other than the stable ones appeared before the random state is achieved. That is, one kind of the unstable $\langle 2', H' \rangle$ sites dominated, then the metastable {T, H} sites appeared. (2) There appeared clear difference in the occupation rule between the $\langle 2', H' \rangle$ and $\langle 1', T' \rangle$ sites. Fig. 1 gives us the details of the synergistic reaction of a crystal according to the ion impacts. The first value of $N_{(1)}(0) = N_{(2)}(0) = 0.5$ implies that the crystal was almost perfect. When irradiation began, atoms were

Fig. 1. The PM of Si atoms at 400 K, as the function of ion impact. The fraction of Si atoms accommodated at the stable (1,2) or the metastable {T,H} sites is shown in (a), while those of the unstable sites <1',2',T',H'> are shown in (b). The corresponding profile of the B atoms at the stable (1,2) or the metastable {T,H} sites is shown in (c).

synergistically moved to the unstable sites, then to the metastable sites. With further irradiation, such a cooperative movement is lost, where crystallinity existed no more.

3.2. The lattice reaction depending on T_h : $N_i(n)$

The rigidity of the target crystal depends on T_h , which is interestingly seen by the PM, as is shown by the

Fig. 2. The T_h dependence of the collapse of the Si crystal, by means of the PM for Si atoms. (a) Stable sites (1,2) and (b) metastable sites {T,H}.

abrupt decrease in Fig. 2a. At $T_h = 100$ K, the crystalline system was transferred almost straightforwardly to a random state, without dominant occupation of the unstable or metastable sites as was shown in Fig. 1. As is shown in Fig. 2b, metastable sites {T,H} grow as T_h increases. At $T_h = 200$ K, this peak was sharp but low; at $T_h = 300$ K, this peak became very sharp and high; then at $T_h = 400$ K it became distinguished. We knew that the reaction mechanism of the crystal definitely changed between 100 and 200 K.

3.3. The agglomeration promoted by the lattice deformation

At $T_h = 100$ K, the Si atoms had moved suddenly from the stable states. At the same time, agglomeration increase significantly progressed. The $k(n)$ defined by Eq. (1) once increased significantly across this critical moment, then decreased. The final decrease implies the dissociation by further ion impact.

Fig. 3 shows the T_h dependence of the $k(n)$. Lines are drawn to guide the eyes. The thick line indicates the case of $T_h = 100$ K, while thinner lines indicate $T_h \geq 200$ K. As a matter of course, both agglomeration and dissociation coexisted during the cluster-growth process and B_n clusters were positively produced at first. After this first stage, the competition between the agglomeration and dissociation became different depending on the T_h . At $T_h = 100$ K, the dissociation overcame the agglomeration finally. On the contrary, when the target was not extremely cold, i.e., $T_h \geq 200$ K, agglomeration looked continuously dominant although a tendency of saturation slightly appears finally. This behavior explained that the radiation annealing practically promoted the agglomeration.

4. Conclusions

We studied the correlation between impurity agglomeration and the crystal damage, by means of the parallel

Fig. 3. The T_h dependence of the index of agglomeration as a function of the ion impacts. The thick line indicates the case of $T_h = 100$ K, the thinner ones from 200 to 400 K. Lines were drawn to guide the eyes.

analysis of a MD and PM [6], in the case of high-dose implantation of B ions into a Si crystal. We prepared a super-saturated B in Si, and examined how the lattice reaction progressed. The defect formation differed definitely between 100 and 200 K. At a low temperature of 100 K, the Si crystal collapsed abruptly at a moment during the ion impacts, then the spatial distribution of the Si atoms turned to be random immediately. Across the critical moment, agglomeration was drastically promoted. However, dissociation overcame the agglom-

eration finally. At temperatures higher than 200 K, such a cooperative response differed, where agglomeration always overcame the dissociation. Therefore, concluding remarks are: (1) The impurity agglomeration is due to the cooperative reaction of the crystal atoms performing long-range interactions. (2) The radiation annealing promoted the agglomeration.

Optical absorption peaks observed in electron-irradiated n-type Si

M. Suezawa^{a,*}, N. Fukata^a, A. Kasuya^b^a *Institute of Materials Research, Tohoku University, 2-1-1 Katahira, Sendai 980-8577, Japan*^b *Center for Interdisciplinary Research, Tohoku University, Sendai 980-8578, Japan*

Abstract

We found many optical absorption peaks in electron-irradiated n-type Si crystals. Specimens were prepared from various Si crystals. After chemical etching, they were irradiated with 3-MeV electrons at RT. Their optical absorption spectra were measured with an FT-IR spectrometer at temperatures in the range of 5 K and RT with a resolution of 0.25 cm^{-1} . Many optical absorption peaks were observed in the wavenumber range between 950 and 1600 cm^{-1} only in n-type (phosphorus-doped) floating-zone grown Si crystals. Hence, they are due to donors. They were not observed in Czochralski-grown Si (CZ-Si) crystals. This suggests that these peaks are due to complexes of phosphorus and vacancies since most vacancies in CZ-Si form pairs (A-center) with oxygen because of very high concentration of oxygen. They disappeared by annealing at above 200°C . © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Electron irradiation; Optical absorption; Donor

1. Introduction

Optical absorption measurements of electron-irradiated silicon crystals have been conducted since the 1950s (see, as a review, Ref. [1]). In these studies, many absorption peaks were observed. Some are due to electronic transitions associated with divacancy, and some are due to vibrational transitions associated with pairs of vacancies and oxygen atoms and so on. We found many optical absorption peaks in electron-irradiated floating-zone grown silicon crystals (FZ-Si). They are probably due to electronic transitions associated with vacancy–phosphorus pairs.

2. Experimental

Specimens used in this study were prepared from FZ-Si crystals of n-type and p-type (boron concentration: $1.5 \times 10^{16}\text{ cm}^{-3}$) and Czochralski-grown Si crystals

(CZ-Si) of n-type (phosphorus concentration: $5.2 \times 10^{15}\text{ cm}^{-3}$). The phosphorus (P) concentrations of the n-type FZ-Si specimens of F1, F2 and F3 were 1.5×10^{16} , 5.8×10^{15} and $2.4 \times 10^{15}\text{ atoms cm}^{-3}$, respectively. We irradiated specimens with 3-MeV electrons at RT and measured the optical absorption spectra of irradiated specimens with an FT-IR spectrometer equipped with a continuous-flow-type liquid helium cryostat in a temperature range between 5 K and RT. The spectral resolution was 0.25 cm^{-1} .

3. Results and discussion

Fig. 1 shows the optical absorption spectrum of electron-irradiated FZ-Si specimen, F1. Many peaks were observed. The spectrum of F2 was similar to Fig. 1. On the other hand, that of F3 showed only two peaks at about 1150.6 and 1156.5 cm^{-1} , which are the strongest peaks in Fig. 1. Other peaks were not observed probably because of small concentrations of defects in this specimen. The peak positions of Fig. 1 are at larger wavenumbers than those due to vibrational transitions except those of hydrogen, nitrogen and oxygen, the

E-mail address: suezawa@imr.edu (M. Suezawa).

Fig. 1. Optical absorption spectrum of the specimen F1 after electron-irradiation of $4 \times 10^{16} \text{ cm}^{-2}$.

concentrations of which are very small in our specimens. Hence, these are due to electronic transitions associated with complexes, which include point defects generated by electron-irradiation of specimens. One evidence for electronic transitions is that these peaks were not observed in irradiated p-type FZ-Si. Complexes responsible for these peaks are thought to include vacancies (V) since these peaks were not observed in CZ-Si. Most vacancies generated by electron-irradiation of CZ-Si crystals are known to form pairs with oxygen atoms and some form divacancies, when the irradiation dose is below 10^{18} cm^{-2} [2]. We tried to classify these peaks assuming the effective-mass theory but were unsuccessful. Hence, we could not determine the number of species of complexes responsible for these peaks. This is discussed later in connection with temperature dependence of the peak intensities.

We propose that complexes responsible for these peaks include V and P according to following discussion. As is well-known, optical absorption peaks due to divacancies are observed at around 2700 cm^{-1} [3] and hence, divacancies are not responsible for these peaks. The probabilities to form complexes larger than divacancy are considered to be low, since the irradiation dose was not large. Hence, complexes composed of only vacancies are not the defects responsible for these peaks. Pairs of V and P, so-called the E-center, are known to be easily formed [4] due to irradiation of P-doped Si. According to a study by means of EPR method, the E-center has an acceptor level at about 0.44 eV below the bottom of the conduction band (E_c) [4]. It is EPR-inactive when the Fermi level is above that level. Kimerling et al. [5] found electron-trap levels at $E_c = 0.11, 0.20, 0.30$ and 0.44 eV in electron-irradiated n-type Si crystals. Some of them may be optically active. We tentatively propose that the V–P pairs in an appropriate charge state are responsible for these peaks. There may be high probability to form V_2P by reaction between an E-center and V. Lugakov and Luk'yanitsa [6] suggested

that the V_2P has acceptor levels at the lower half of the band gap. If this is the case, V_2P complexes are not responsible for our spectrum.

We should compare the above spectrum with that observed in neutron-irradiated Si. More than 40 optical absorption peaks, so-called the higher-order band (HOB), were found in neutron-irradiated Si crystals in the wavenumber range from 650 to 1300 cm^{-1} [7]. Their peak positions are different from those of Fig. 1. Moreover, as shown later, their thermal stability is also much different from those of Fig. 1. Hence, we conclude that the above peaks are different from the HOB.

Fig. 2 shows dependence of the intensity of the 1156.5 cm^{-1} peak in various specimens on the electron dose. In the case of specimens, F1, there is a peak at a dose of around $6 \times 10^{16} \text{ cm}^{-2}$. This peak seems to shift to lower doses as the phosphorus concentration becomes smaller as suggested from curves of F2 and F3. At low doses, the peak intensity of F1 increased as the dose increased probably due to the increase of V–P pairs. We should recollect our previous results in relation to this interpretation. As shown in a separate paper [8], we studied the formation of VH_2 complex due to electron-irradiation of hydrogen-doped Si crystals. The concentration of VH_2 complex increased as the irradiation dose increased in high-purity Si. On the other hand, it was very small in the specimen F1 doped with H. These results suggest that a V in the specimen F1 preferentially form a pair with a P and not with an H_2 . At doses higher than about $6 \times 10^{16} \text{ cm}^{-2}$, the intensity in the specimen F1 decreased as the dose increased. The dependences of the specimens F1, F2 and F3 on the electron dose are similar to each other at high doses: the slopes of curves in Fig. 2 was almost -1 . This is probably due to the saturation of V–P pair and the increase of acceptors formed by electron-irradiation. According to our experiment [9], the concentration of acceptors at the irradiation dose of $1 \times 10^{16} \text{ cm}^{-2}$ was about $9 \times 10^{14} \text{ cm}^{-3}$ and increased almost proportional to the

Fig. 2. Dependences of the intensity of the 1156.5 cm^{-1} peak in the specimens F1, F2 and F3 on the electron dose.

electron-dose. Hence, if the concentration of V-P pair is saturated at high doses, that of the appropriate charge state, which is responsible for the above optical absorption peaks decreases as the dose increases. Within our knowledge, the spectrum of Fig. 1 has not been reported even though a lot of studies have been performed for electron-irradiated Si crystals by means of optical absorption measurement method. This is probably due to the behavior shown in Fig. 2: Irradiation doses so far adopted were rather high, around 10^{18} cm^{-2} , and hence, the absorption intensities should have been very weak.

Fig. 3 shows the annealing behaviors of the 1156.9 cm^{-1} peak. The annealing duration was 30 min at each temperature. The peak intensity almost disappeared due to annealing at 225°C . This annealing stage agrees well with the second stage observed by Hirata et al. [10] in γ -irradiated n-type Si. According to them, this annealing stage is due to diffusion of V-P pairs to the sinks. In the case of the HOB, it is observed after annealing at $450\text{--}600^\circ\text{C}$ [7]. Hence, as indicated already, the HOB is different from our peaks.

We measured the dependence of peak intensities on the measurement temperature to determine the energy levels of the ground states of those peaks. The measured temperature range was too narrow to exactly determine those levels. It was clarified, however, that the dependences of intensities of the 1150.6 and 1156.5 cm^{-1}

Fig. 3. Isochronal annealing behavior of the 1156.5 cm^{-1} peak due to annealing for 30 min at each temperature.

peaks, of the 1309.2 , 1312.5 and 1316.2 cm^{-1} peaks and of the 1563.3 cm^{-1} peak on temperature were similar. It means that the energy levels of these ground states are the same. Hence, we tentatively propose that the observed peaks are due to one kind of center, the V-P pair at an appropriate charge state. To clarify the properties of the ground state, further studies by means of EPR and DLTS methods are necessary.

4. Summary

We found many optical absorption peaks in electron-irradiated FZ-Si crystals of n-type only. They were not observed in electron-irradiated CZ-Si crystals. We proposed that these optical absorption peaks were due to electronic transitions of V-P pair in an appropriate charge state.

Essential difference in concentration profile of Au in Si after annealing above or below 850°C

Masami Morooka*

Fukuoka Institute of Technology, Wajirohigashi, Higashi-ku, Fukuoka 811-0295, Japan

Abstract

Indiffusion and out-diffusion profiles of Au in Si have been measured after a heat treatment at a higher or lower temperature than 850°C. The diffusion is slow and the profiles show a typical kick-out diffusion, in both heat treatments for the indiffusion above and below 850°C, and for the out-diffusion of Au supersaturated above 850°C. On the other hand, the out-diffusion of Au supersaturated below 850°C is very fast and the profile shows that it is flat. The essential difference in the concentration profiles are consistent with the change of the Au configuration supersaturated below 850°C from high-temperature substitutional Au to a low-temperature one. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si: Au; Concentration profile of Au in Si; Impurity diffusion in Si; Gold state in silicon

1. Introduction

Au atoms in Si occupy interstitial and substitutional sites, and the substitutional Au exists in three states: low-temperature substitutional Au, high-temperature substitutional Au, and agglomerations of substitutional Au [1]. High-temperature substitutional Au diffuses slowly itself, and their atomic-flow is dominated by an interchange mechanism of Si atom with interstitial Au atom [2]. On the other hand, low-temperature substitutional Au diffuses rapidly by a ring mechanism [3] and their atomic-flow is limited by the diffusion itself [4]. The author et al. have reported that the annealing characteristics [5] resulting in the out-diffusion profile [6] of supersaturated substitutional Au in Si are affected dominantly by cooling down to room temperature or not before the heat-treatment for annealing, namely, they are fast and flat type or slow and inverse U-type corresponding to the diffusion of low-temperature substitutional Au or a high-temperature one, respectively.

In this paper, indiffusion and out-diffusion profiles of substitutional Au in Si have been measured after a heat

treatment at a higher or lower temperature than 850°C, which is the boundary temperature to change the gold configuration from high-temperature substitutional Au to a low-temperature one. The experimental results are consistent in that the excess over the thermal equilibrium concentration, namely, the amount of supersaturated Au atoms, change from high-temperature substitutional Au to a low-temperature one by cooling below 850°C after a pre-indiffusion.

2. Experimental details

Float-zoned (Fz) and extended-defect-free silicon crystals of about 1 mm thickness were used. About several tens nm of Au layers were evaporated on both surfaces of the specimen before heat treatment. In the experiment for the measurement of indiffusion profile, the specimens were heat-treated at 800°C or 900°C for 90 h. In one experiment for measurement of out-diffusion profile, specimens were heat-treated at 1150°C for 90 h for pre-indiffusion of Au, and one of them is used for the measurement of indiffusion profile, which is regarded as the initial profile for subsequent annealing. Au layers were evaporated again after removal of surface layers of the pre-indiffused specimen

E-mail address: morooka@ce.fit.ac.jp (M. Morooka).

to transform the surface concentration into the thermal equilibrium value in the subsequent heat treatment [7], and the specimen was heat-treated at 800°C or 900°C for 90 h subsequent to re-heat-treatment at 1150°C for 30 min. In this case, specimen temperature decreases from 1150°C to the annealing temperature, and, substitutional Au supersaturated at the temperature are annealed out during the heat-treatment. In the other experiment for the measurement of out-diffusion profile, the specimen, on which Au layers were evaporated after the pre-indiffusion, was heat-treated directly at 800°C or 900°C for 90 h from room temperature without re-heat-treatment at 1150°C. In this case, the specimen is cooled to a room temperature before the annealing, and, substitutional Au supersaturated at the room temperature are annealed out during the heat treatment.

The concentration profile of substitutional Au is obtained by a capacitance measurement in lines with Au–Si Schottky diodes on an angle-lapped surface [8].

3. Experimental results

3.1. Indiffusion profiles at 800°C and 900°C

The concentration profiles of substitutional Au in Si after heat-treatment for indiffusion at 800°C for 90 h or at 900°C for 90 h are shown in Fig. 1. The indiffusion is very slow at the temperatures, and, at 800°C, the concentration is difficult to measure except near the specimen surface due to a concentration lower than the detection limit of our apparatus. Both indiffusion profiles seem to show a kick-out diffusion limited by the self-interstitial diffusion to the specimen surface, namely, a U-shaped profile.

Fig. 1. Indiffusion profiles of substitutional Au in Si at 800°C and 900°C. The specimen thickness is about 1 mm.

3.2. Out-diffusion profiles at 800°C and 900°C

The concentration profiles of supersaturated substitutional Au in Si after heat-treatment at 800°C or 900°C for 90 h subsequently to re-heat-treatment at 1150°C for 30 min after the pre-indiffusion at 1150°C for 90 hours are shown in Fig. 2. The out-diffusion at 900°C is very slow and shows a typical kick-out diffusion, namely, an inverse U shape. On the other hand, at 800°C, the annealing is very fast in spite of the temperature lower than 900°C, and the profile shows a flat one due to homogeneous agglomeration of Au atoms [4]. The initial profile predicted from the profile of other specimens is shown in the figure.

3.3. Out-diffusion profiles at 800°C and 900°C without re-heat-treatment at 1150°C

The concentration profiles of supersaturated substitutional Au in Si after heat-treatment at 800°C or 900°C for 90 h after quenching to room temperature subsequent to the pre-indiffusion at 1150°C for 90 h are shown in Fig. 3. In this case, the out-diffusion even at 900°C is very fast additional to that at 800°C, and, both profiles below and above 850°C show a flat-type one due to the homogeneous agglomeration.

4. Discussion

To compare the indiffusion and out-diffusion characteristics, Figs. 1 and 2 are plotted together in Fig. 4.

Fig. 2. Out-diffusion profiles of supersaturated substitutional Au in Si at 800°C and 900°C after re-heat-treatment at 1150°C for 30 min. The specimen thickness is about 1 mm.

Fig. 3. Out-diffusion profiles of supersaturated substitutional Au in Si at 800°C and 900°C without re-heat-treatment at 1150°C. The specimen thickness is about 1 mm.

Fig. 4. Indiffusion and out-diffusion profiles of substitutional Au in Si. Data in Figs. 1 and 2 are re-plotted together in the figure for the comparison. The solid lines show the approximate equations for kick-out diffusion, Eqs. (1) or (2), using D^* as a fitting parameter.

The indiffusion profile at 900°C shows a U-shaped one, and even that at 800°C seems to show a U shape. Vacancy mechanism is dominant in the interstitial-substitutional impurity diffusion in Si below 950°C according to Frank et al. [9], nevertheless, self-interstitial seems to be dominant still at 800°C in our case. Therefore, the indiffusion of substitutional Au in Si below and above 850°C is limited by the diffusion of

self-interstitials to the specimen surface, and, Au indiffusion seems to occur via a kick-out mechanism independent of the indiffusion temperature. The out-diffusion profile at 900°C shows an inverse U shape, and the out-diffusion of substitutional Au supersaturated above 850°C is limited by the diffusion of self-interstitials from the surface, namely, also by the kick-out mechanism.

An approximate equation for the kick-out diffusion can be obtained for the indiffusion or for the out-diffusion as follows:

$$C = C_0(1 + L/\sqrt{tD^*})/(2 + L/\sqrt{tD^*})[1/(1 + x/\sqrt{tD^*}) + 1/\{1 + (L - x)/\sqrt{tD^*}\}] \quad (1)$$

or

$$C = C_0 - (C_i - C_0)(1 + L/\sqrt{tD^*})/(2 + L/\sqrt{tD^*}) \times [1/(1 + x/\sqrt{tD^*}) + 1/\{1 + (L - x)/\sqrt{tD^*}\}], \quad (2)$$

respectively, in the same way as for Eq. (43) in reference [10]. Here, the equations are multiplied by $(1 + L/\sqrt{tD^*})/(2 + L/\sqrt{tD^*})$ to fit the surface concentration, and the factor proposed by Morooka previously [7] is misprinted. C_0 , C_i , L , t , D^* and x show surface and initial concentrations, specimen thickness, time, a constant related to diffusion, and distance from the surface, respectively. D^* includes C_i and diffusion constant, furthermore, the equations are not so good in the case of a long diffusion time, therefore, the equations are not enough to discuss about a diffusion constant and are useful to distinguish the diffusion mechanism. The solid lines in Fig. 4 show Eqs. (1) or (2) for $C_0 = 10^{15} \text{ cm}^{-3}$ at 800°C and $C_0 = 9 \times 10^{15} \text{ cm}^{-3}$ at 900°C. C_i , L and t are used experimental values and D^* is used as a fitting parameter. The surface concentrations are a little larger than the solid solubility of Au in Si obtained by Stolwijk et al. [11].

On the other hand, the out-diffusion profile at 800°C shows a flat-type one in contrast to the out-diffusion at 900°C. The flat profile is a characteristic of the annealing of supersaturated low-temperature substitutional Au in Si due to the ring diffusion accompanied by a homogeneous agglomeration [4]. In this case, the annealing time of 90 h is long enough to recover the thermal equilibrium concentration at 800°C, and, the flat concentration is regarded as the solid solubility. The surface concentration in the indiffusion profile at 800°C is predicted to increase to the solubility.

The specimens used for the measurement shown in Fig. 3, were heat-treated at the annealing temperature directly from room temperature. In this case, substitutional Au supersaturated at room temperature, namely, below 850°C, are heat-treated at the annealing temperature. Therefore, the profile even at 900°C shows an out-diffusion profile for the low-temperature substitutional

Au, and shows a flat and fast one. The annealing time is also long enough to recover thermal equilibrium concentration at 900°C, and the flat concentration at 900°C is regarded as the solid solubility, which is the same as the surface concentration in the indiffusion profile at 900°C.

It is expected that, the total concentration of Au is nearly equal to the concentration of substitutional Au in the kick-out diffusion, namely, in the indiffusion below and above 850°C and in the out-diffusion supersaturated above 850°C, however, the total concentration is much larger than the substitutional Au in the flat and fast diffusion, namely, in the out-diffusion supersaturated below 850°C [7].

5. Conclusions

- (1) Substitutional Au in Si shows a concentration profile of slow and U or inverse U shape, in the case of indiffusion below and above 850°C, and in the case of out-diffusion supersaturated above 850°C.
- (2) Substitutional Au in Si shows a concentration profile of fast and flat shape, in the case of out-diffusion supersaturated below 850°C.
- (3) The above experimental results are consistent with the change of diffusion mechanism, namely, that the excess over the thermal equilibrium concentration of substitutional Au change the configuration from high-temperature substitutional Au to a low-temperature one by cooling below 850°C after a pre-indiffusion.

Abstract

Interactions between the oxygen dimer (O_{2i}) and silicon self-interstitials (I) and vacancies (V) have been studied in Czochralski-grown silicon (Cz-Si) crystals using infrared absorption and deep level transient spectroscopies. The focus in this report is on reactions of O_{2i} with I. The first step in this interaction is found to be the formation of a self-interstitial-dioxygen centre (IO_{2i}) with oxygen-related local vibrational mode (LVM) bands at 922 and 1037 cm^{-1} . During the second formation step, another centre, I_2O_{2i} , with LVM bands at 918 and 1034 cm^{-1} is suggested to appear. A Si-related band at about 545 cm^{-1} is also assigned to both the IO_{2i} and I_2O_{2i} centres. The IO_{2i} centre is found to be electrically active with an acceptor level at $E_c - 0.11$ eV. The both defects, IO_{2i} and I_2O_{2i} , are stable at room temperature and anneal out at about 400 and 550 K, respectively. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Self-interstitials; Oxygen; Electron irradiation

1. Introduction

Silicon wafers used for integrated circuits require the presence of oxygen, due to its beneficial effects such as wafer hardening and intrinsic gettering [1,2]. The most common material, Czochralski-grown silicon, typically contains $\sim 10^{18} cm^{-3}$ of interstitial oxygen atoms (O_i) and is in a very large temperature range highly supersaturated. As a consequence clustering of oxygen atoms occurs, resulting in formation of different oxygen complexes from small clusters like dimers, trimers (O_{3i}) to oxygen-related thermal double donors (TDDs) and quartz precipitates.

It was found that oxygen atoms as well as oxygen-related complexes could interact with intrinsic defects of Si lattice, vacancies (V) and self-interstitials (I) [1,2]. V and I can be easily created upon irradiation of Si crystals with high energy particles (electrons, protons, ions, etc.). Electron-irradiated Cz-Si was a subject of many investigations [3–10]. Several oxygen-vacancy (V_nO_n) complexes have been identified, but very few complexes incorporating oxygen atoms and self-interstitials are known. Experimental studies of samples irradiated at around 80 K have showed that O_i can trap I and form IO_i complex [11–14], which is stable below 300 K. This defect has been found to trap an additional I and form I_2O_i [15,16].

Silicon self-interstitials were suggested to play an important role in the formation of oxygen-related TDDs [17,18]. The structure of these complexes, which were discovered almost 50 years ago is still a matter of debate.

*Corresponding author. Tel.: +46-46-2220929; fax: +46-46-2223637.

E-mail address: lennart.lindstrom@ftf.lth.se (J.L. Lindström).

According to one of the most popular models of TDDs, their core consists of a complex of two oxygen atoms and a silicon self-interstitial ($O_{2i}I$) [17]. The $O_{2i}I$ was suggested to be a double donor.

Recently, local vibrational mode bands due to oxygen dimers were identified in Si [19–21], and a method of enhanced formation of O_{2i} complexes was proposed [22,23]. In this work we present results of infrared (IR) absorption and deep level transient spectroscopy (DLTS) studies of interaction of oxygen dimers with V and I in electron- and gamma-rays-irradiated Cz-Si crystals.

2. Experimental

The samples used in this investigation were as-grown Cz-Si, doped with phosphorus to resistivities of about $60\ \Omega\text{cm}$. The concentrations of interstitial oxygen (O_i) and substitutional carbon (C_s) were monitored by measuring the well-known absorption bands at 1107 cm^{-1} [24] and 605 cm^{-1} [9], respectively. We also included samples doped with the isotope ^{18}O . The samples were polished to an optical surface on two sides and the dimensions were $10 \times 5 \times 3\text{ mm}^3$. The electron irradiation was performed in a temperature regulated holder in air at temperatures in the range $320\text{--}650\text{ K}$ to different doses from 5×10^{16} to $4 \times 10^{18}\text{ cm}^{-2}$, using 2.5 MeV electrons. The beam current was in the range $1\text{--}12\text{ mA/cm}^2$. Some samples were irradiated with gamma-rays from a ^{60}Co source. Heat-treatments (HTs) were performed in a nitrogen ambient or in air.

IR absorption studies of LVMs were carried out using Fourier Transform IR (FT-IR) spectrometers. A spectral resolution of $0.5\text{--}1.0\text{ cm}^{-1}$ was used and the samples were measured at 10 K and at RT. DLTS measurements were carried out using a Semitrap DLS-83D system. Capture cross sections of electrons by deep traps (σ_n) were determined from the analysis of trap filling process upon applying pulses of different lengths. Gold Schottky diodes were prepared for the measurements.

3. Results and discussion

3.1. Formation of the oxygen dimer

Since the concentration of oxygen dimers in as-grown Cz-Si crystals is relatively low (around $1 \times 10^{15}\text{ cm}^{-3}$) and IR studies of LVM bands typically require defect concentrations an order of magnitude higher for detailed investigations, a special technique has been developed [22,23], where the dimers are produced by electron irradiation (MeV) at about 650 K in carbon-

lean material through the reaction

Using this technique we could prepare silicon samples with the dimer concentration up to $5 \times 10^{16}\text{ cm}^{-3}$. It has been found that there is a considerable difference between carbon-lean and carbon-rich CZ-silicon in terms of possible reactions during irradiation [22,23]. The effective interaction of self-interstitials with substitutional carbon atoms according to the Watkins replacement mechanism,

is the main reason for that. One consequence of the self-interstitial-carbon interaction is that a high concentration of oxygen dimers according to (1) cannot be achieved in carbon-rich silicon. Another efficient trap for I is the vacancy-oxygen centre (VO) through the reaction

3.2. Irradiation of dimer-rich samples at 300 K

In carbon-lean silicon samples irradiated at 650 K the VO concentration after irradiation is much lower than the concentration of O_{2i} and the main traps for I at a repeated irradiation at 300 K will therefore initially be according to

The IO_i complex is not stable above 300 K , so reactions (4) and (5) are not effective during the irradiation at 300 K and the main reactions should be (6), (7) and (1). The further irradiation at 300 K will, however, lead to a rapidly increasing concentration of VO centres due to the dominating concentration of O_i and reaction (3) will very soon compete with reactions (6), (7) and (1). One can compare the concentration of O_{2i} (1012 cm^{-1} band) in as-grown samples and after irradiation at 350°C ($F = 8 \times 10^{17}\text{ e/cm}^2$) by an examination of spectra 1 and 2 in Fig. 1. The strong increase in $[O_{2i}]$ after the irradiation makes its concentration comparable to that of the VO_2 complex (889 cm^{-1} band). The well-known VO-related band at 830 cm^{-1} is not seen in the spectrum 2. Several new bands are appearing in absorption spectra after subsequent irradiation at room temperature (spectra 3–10 in Fig. 1). After irradiation with a fluence of $5 \times 10^{16}\text{ e/cm}^2$, absorption bands at 911 and 1034 cm^{-1} are seen (spectrum 4 in Fig. 1), further irradiation leads to the development of bands at 916

Fig. 1. Room temperature absorption spectra for C-lean n-Cz-Si ($\rho = 50 \Omega \text{ cm}$): (1) as-grown; (2) after electron irradiation at 350°C , $F = 8 \times 10^{17} \text{ cm}^{-2}$; (3–10) after RT irradiation, $F(\text{cm}^{-2})$: (3) 1×10^{16} , (4) 5×10^{16} , (5) 10^{17} , (6) 2×10^{17} , (7) 4×10^{17} , (8) 7×10^{17} , (9) 1.1×10^{18} , (10) 6×10^{18} .

Fig. 2. Generation kinetics of some radiation-induced oxygen-related complexes upon electron irradiation at room temperature of a dimer-rich Cz-Si sample.

and 1031 cm^{-1} (spectra 6–10 in Fig. 1). It is suggested that the first pair of bands appears when IO_{2i} starts to form according to reaction (6) and after that reaction (7) can be activated resulting in the formation of I_2O_{2i} . There is also a weak band at 540 cm^{-1} , the development of which seems to correlate with that of the above mentioned pairs of bands. As the irradiation fluence increases the concentration of the vacancy-oxygen complex grows rapidly and the VO-related line at 830 cm^{-1} dominates in the spectra soon (spectra 6–10 in Fig. 1). This is also illustrated in Fig. 2, where the dose dependencies of the integrated intensities of the considered bands are shown. The observed dependencies can be described by reactions (1), (3), (6) and (7) taking

Fig. 3. Absorption spectra measured at 10 and 300 K for a C-lean Cz-Si sample after two-step electron irradiation: at 350°C with a fluence of 8×10^{17} and at RT with a fluence of $7 \times 10^{17} \text{ cm}^{-2}$.

into account differences in capture cross sections of self-interstitials by VO, VO_2 , O_{2i} , and IO_{2i} complexes.

An analysis of absorption spectra of irradiated oxygen-dimer-rich samples doped with ^{18}O reveals that the pairs of bands at 911 and 1034 cm^{-1} , and at 916 and 1031 cm^{-1} are oxygen-related LVMs, while the weak band at 540 cm^{-1} does not show any shift upon replacement of oxygen isotopes and therefore is suggested to be a Si-related LVM. In Fig. 3 one can see the temperature shifts of the bands upon the change of measurement temperature from 300 to 10 K. The band at 911 cm^{-1} shifts to 922 cm^{-1} , while the band at 916 cm^{-1} shifts to 918 cm^{-1} with the decrease of the measurement temperature. Typical shifts of oxygen-related LVMs in this wavenumber range is about 5–6 cm^{-1} . Exceptions are the LVMs at 1012 and 1060 cm^{-1} due to the oxygen dimer, the temperature shifts of which are extremely small (Fig. 3) [25].

3.3. Annealing studies

In order to investigate the thermal stability of the new defects (IO_{2i} and I_2O_{2i}), an isochronal annealing study has been done. Absorption spectra of an electron-irradiated sample after isochronal anneals are shown in Fig. 4. An examination of the spectra shows that the first appearing defect, IO_{2i} , has completely annealed out at 160°C and the second one, I_2O_{2i} , at 250°C . Disappearance of the IO_{2i} and I_2O_{2i} complexes is accompanied by an increase in intensities of the bands at 1012 and 1060 cm^{-1} due to the oxygen dimer, suggesting that reactions (6) and (7) have corresponding back-reactions. Self-interstitials released according to these back-reactions can take part in reactions like (1) and (3). Several other relatively weak bands have been observed upon

Fig. 4. Absorption spectra at 10 K for Cz-Si: (1) after two-step electron irradiation (350°C , $F = 8 \times 10^{17} + \text{RT}$, $F = 7 \times 10^{17} \text{ cm}^{-2}$) and at different stages of 20 min isochronal anneal, (2) 120°C , (3) 160°C , (4) 210°C , (5) 250°C , (6) 300°C , (7) 350°C .

annealing of the irradiated dimer-rich samples and an investigation of these bands is in progress. After anneals at higher temperatures the band at 895 cm^{-1} due to the VO_2 complex appears in the spectra (spectra 6 and 7 in Fig. 4).

3.4. Irradiation of as-grown materials

Simultaneously, with the irradiation of dimer-rich samples at 300 K, an as-grown sample with a high concentration of O_i ($1.3 \times 10^{18} \text{ cm}^{-3}$) and a very low carbon content ($< 10^{15} \text{ cm}^{-3}$) has been irradiated. Infrared absorption spectra for this sample are shown in Fig. 5. Weak bands have appeared after irradiation at the same positions as in dimer-rich samples. This result shows that in as-grown carbon-lean Cz-Si samples oxygen dimers are effective traps for self-interstitials at initial stages of electron irradiation.

3.5. DLTS results

It was found that DLTS spectra of electron- or gamma-rays-irradiated carbon-lean Cz-Si samples differ significantly from those of Cz-Si samples containing carbon. This difference is clearly seen in Fig. 6, where DLTS spectra in the temperature range 60–120 K for Cz-Si samples irradiated with gamma-rays from a ^{60}Co source are presented. The irradiation of a carbon-lean sample resulted in introduction of two dominant deep level centres with peak maxima at about 73 K (E_{73}) and 93 K (E_{93}) (spectrum 2 in Fig. 6), while for a sample with higher concentration of carbon only one dominant centre (E_{93}) is observed (spectrum 1 in Fig. 6). Fig. 7 shows Arrhenius plots of T^2 -corrected emission rates for both dominant centres induced by the irradiation.

Fig. 5. Absorption spectra at 10 K for electron irradiated (RT, $F = 5 \times 10^{16} \text{ cm}^{-2}$) as-grown Cz-Si crystals with low ($< 10^{15} \text{ cm}^{-3}$, spectra 2 and 3) and intermediate carbon content ($5 \times 10^{16} \text{ cm}^{-3}$, spectrum 1). Spectrum 3 is a difference between the spectra of irradiated and as-grown samples.

Fig. 6. DLTS spectra of Cz-Si samples with different carbon concentration after irradiation with gamma-rays from a ^{60}Co source. N_C : (1) $5 \times 10^{16} \text{ cm}^{-3}$, (2) $< 1 \times 10^{15} \text{ cm}^{-3}$. Fluence of irradiation was $5 \times 10^{16} \text{ cm}^{-2}$.

Activation energies for electron emission (E_n) were found to be 0.163 ± 0.001 and $0.128 \pm 0.001 \text{ eV}$ for E_{93} and E_{73} traps, respectively. Based on the comparison of the obtained trap parameters (E_n and σ_n) with those known from the literature on radiation-induced centres in Cz-Si [26,27], E_{93} peak was assigned to the oxygen-vacancy pair [3,4]. It was found that the electron capture cross section for the E_{73} trap is temperature dependent. The energy barrier for the electron capture was estimated to be about 0.02 eV. Taking this into account, the position of an energy level of the E_{73} trap was determined as $E_c - 0.11 \text{ eV}$. The obtained parameters of the E_{73} trap do not coincide with those of any known radiation-induced traps stable at room temperature

Fig. 7. Arrhenius plot of T^2 -corrected electron emission rates from (1) E_{73} and (2) E_{93} traps.

Fig. 8. Isochronal annealing behaviour (1) of the concentration of a centre with an acceptor level at $E_c - 0.11$ eV and (2) of the integrated intensity of the absorption band at 922 cm^{-1} .

[26,27]. The effect of electric field on the electron emission rate from the E_{73} trap is found to be negligible, indicating that the centre is of acceptor nature.

An isochronal annealing study shows that the E_{73} trap anneals out in the temperature range of 100–150°C and the elimination process is very similar to that of the defect responsible for the 922 and 1037 cm^{-1} lines in the absorption spectra (Fig. 8). Based on the similarities in formation and annealing conditions it is suggested that the E_{73} trap is the same as a centre giving rise to the 922 and 1037 cm^{-1} lines in IR absorption spectra of irradiated carbon-lean Cz-Si samples.

3.6. Uniaxial stress and an atomic model of IO_{2i} complex

It was found from uniaxial stress measurements that the 918 and 922 cm^{-1} lines show the same splitting

behaviour. The polarisation of the components strongly indicates that the symmetry of centres is monoclinic I or lower. All the obtained experimental results are well in line with preliminary theoretical calculations for the IO_{2i} centre which points to a defect made up of a staggered oxygen dimer and a $\langle 110 \rangle$ -split self-interstitial [28].

3.7. Other self-interstitial-oxygen complexes

During irradiation at 650 K there is a band appearing at 1006 cm^{-1} which has been suggested to be related to the oxygen trimer, O_{3i} [29]. This band can be observed in Fig. 4 as well as two bands at 956 and 1054 cm^{-1} , appearing together with the bands due to the IO_{2i} and I_2O_{2i} . An analysis of the spectra in Fig. 4 shows that the intensity of the 1006 cm^{-1} band increases upon disappearance of the bands at 956 and 1054 cm^{-1} . It is suggested that the O_{3i} can also trap self-interstitials and the pair of lines at 956 and 1054 cm^{-1} is tentatively assigned to an IO_{3i} complex.

4. Summary

During electron irradiation at 300 K of oxygen-rich carbon-lean samples a new group of defects has been revealed by IR spectroscopy. These defects are suggested to be formed by reactions between oxygen dimers and silicon self-interstitials. The first step in these reactions is the formation of the IO_{2i} centre with oxygen-related LVMs at 922 and 1037 cm^{-1} . The second step is the formation of the I_2O_{2i} centre with the corresponding LVMs at 918 and 1034 cm^{-1} . A Si-related band at 545 cm^{-1} is common for both the complexes. Annealing studies of these centres show that the IO_{2i} anneals out below 450 K and the I_2O_{2i} below 550 K.

An acceptor level at $E_c - 0.11$ eV has been identified as related to the IO_{2i} complex on the basis of similarities in the formation and annealing behaviour of the level and the absorption bands at 922 and 1037 cm^{-1} . According to preliminary ab initio calculations [28], the obtained experimental characteristics of the IO_{2i} centre are consistent with those expected for a complex incorporating a staggered oxygen dimer and $\langle 110 \rangle$ -split silicon self-interstitial.

Abstract

The local vibrational modes of thermal double donors in Si and Ge are investigated by FTIR and ab initio modelling. At most, two oxygen modes are detected from each donor, which exhibit regular shifts with increasing donor number. By using mixtures of ¹⁶O and ¹⁸O, it is found that in Si the upper band does not yield any new modes suggesting that any oxygen atom is decoupled from any other. However, the lower frequency bands exhibit unique mixed modes proving for the first time that oxygen atoms are coupled together and in close spatial proximity. Ab initio calculations demonstrate that the modes and their isotopic shifts are consistent with a model involving two parallel chains of oxygen atoms linking second neighbour Si atoms, terminated by O-atoms close to the normal position for interstitial O. © 2001 Elsevier Science B.V. 1. Introduction

Heating oxygen rich silicon or germanium between 300°C and 500°C leads to the formation of a family of double donors called thermal double donors (TDD) [1–3]. They are believed to consist of oxygen atoms possibly linked with self-interstitials [4–9]. In this paper, we describe the results of infra-red absorption experiments and first principles modelling of the local vibrational modes (LVMS) of TDD(*N*) in both Si and Ge. Although thermal donors in Ge have received less

attention, the weaker background absorption and the high concentrations of TDD which can be introduced, makes it a particularly fruitful material to investigate.

Recently, two sets of vibrational bands have been assigned to the early members of the TDD family. These lie around 1000 and 750 cm⁻¹ in Si [10,11], and 780 and 600 cm⁻¹ in Ge [12–15]. The participation of oxygen in the modes is confirmed by isotopic shifts with ¹⁸O. The observation of only two modes in each donor appears to be inconsistent with the model whose family members differ by the number of oxygen atoms [5,7,8,16], and offers indirect support to the self-interstitial model [6,4]. In this paper we report new infra-red data on the donors in Si and Ge. Further, we demonstrate that the observed modes, perhaps surprisingly, can be understood from

an oxygen-only model, without the need for self-interstitials.

2. Experimental and theoretical details

In this study, three types of Si and Ge samples were used. The first (1) contained ^{16}O , while the second (2) mainly contained ^{18}O . The third (3) was co-doped with ^{16}O and ^{18}O . Concentrations of ^{16}O (^{18}O) were monitored by measuring the intensities of the absorption bands at 1107 (1058) and 856 (812) cm^{-1} in Si [17] and Ge [18], respectively. Thermal donors were generated by heating Ge and Si samples at 370°C and 420°C in air. The IR absorption measurements were carried out at 10 and 300 K using a Bruker 113v Fourier transform IR spectrometer. The spectral resolution was 0.5 or 1.0 cm^{-1} .

The vibrational modes of the model were found using 112 atom supercells and an ab initio total energy local density functional code (AIMPRO) [19]. The code evaluates the dynamical matrix of the defect from which the vibrational modes and their normal coordinates can be found. Previous studies indicate that the errors in the frequencies lie around 10%. A large complex involving a chain of Si–O–Si units possesses a great number of local modes, and only a few are detected. To ascertain the most intense modes we placed a charge Q on each O atom, and a charge $-mQ/2$ on each Si neighbour bonded to m O-atoms. The intensity of the mode is then related to the change in the dipole moment of the defect when the atoms are displaced according to their normal coordinates. Tests with other reasonable charge distributions did not lead to significant differences.

3. Results and discussion

Fig. 1 shows fragments of differential absorption spectra of Si:O samples heat-treated at 420°C for

Fig. 1. Absorption spectra measured at 300 K for Si:O samples heat-treated at 420°C for 15 h: (1) $[\text{O}] = 1.3 \times 10^{18} \text{ cm}^{-3}$; (2) $[\text{O}] = 1.5 \times 10^{18} \text{ cm}^{-3}$; (3) and (4) $[\text{O}] = 8 \times 10^{17} \text{ cm}^{-3}$, $[\text{O}] = 7 \times 10^{18} \text{ cm}^{-3}$. The spectrum of a non-annealed sample was used as a reference in 4.

15 h. A signal recorded from a high-purity float-zone Si sample was subtracted from each spectrum. In all the samples (^{16}O , ^{18}O and $^{16}\text{O} + ^{18}\text{O}$), bands due to oxygen dimer, TDD(2) and TDD(3) (1013, 988 and 999 cm^{-1} , respectively), appear to be the dominant defects. The bands related to TDD are positioned in the wavenumber regions of 945–1000, 700–730 and 575–580 cm^{-1} . The TDD band at 580 cm^{-1} is reported for the first time. A clear linear correlation was found between the integrated intensity of this band and that of the bands at about 1000 and 750 cm^{-1} . All of these bands possess similar formation and annealing kinetics. The band at 580 cm^{-1} shows only a weak shift to higher frequencies with an increase in the TDD number, and is practically insensitive to an oxygen isotope substitution. In contrast, the 750 and 1000 cm^{-1} -bands undergo substantial shifts. It should be noted, however, that the ^{18}O isotope shift of the 750 cm^{-1} -bands is less than that of the 1000 cm^{-1} -bands ($^{16}\text{O}/^{18}\text{O} = 1.03$ and 1.045, respectively). By using mixtures of ^{16}O and ^{18}O , it is found that in Si the upper band does not yield any new modes suggesting that any oxygen atom is decoupled from any other. However, the lower frequency bands exhibit unique mixed modes proving for the first time that oxygen atoms are coupled together and in close spatial proximity.

Similar results have also been obtained for the 600 cm^{-1} -band in Ge co-doped with ^{16}O and ^{18}O (see Fig. 2), i.e., a unique mixed mode at about 595 cm^{-1} is observed after HT at 370°C for 15 h. However, unlike in Si, a mixed mode also appears in the upper band region at 755 cm^{-1} , along with ^{16}O and ^{18}O modes at 780 and 742 cm^{-1} .

Calculations of the vibrational spectra were based on a TDD model shown in Fig. 3(a), and discussed elsewhere at this conference [9]. Here, the core of TDD(N) consists of two parallel [110] chains of oxygen atoms bonded with second neighbour Si atoms (denoted

Fig. 2. Absorption spectra measured at 300 K for Ge:O samples heat-treated at 370°C for 20 h: (1) $[\text{O}] = 2.3 \times 10^{17} \text{ cm}^{-3}$; (2) $[\text{O}] = 3.2 \times 10^{17} \text{ cm}^{-3}$; (3) $[\text{O}] = 2.3 \times 10^{17} \text{ cm}^{-3}$, $[\text{O}] = 1.7 \times 10^{17} \text{ cm}^{-3}$.

Fig. 3. (a) O_7 -2NN double donor. The white and black circles denote Si and O atoms, respectively. The two observed O-bands in TDD(N) at ~ 750 and ~ 1000 cm^{-1} in Si (~ 600 and ~ 780 cm^{-1} in Ge), are assigned to chain and end oxygen modes shown in (b) and (c) respectively.

by O -2NN). The ends consist of oxygen atoms bonded to neighbouring Si atoms denoted by O -1NN and their interface must necessarily contain over-coordinated O atoms. The O_n -2NN chain possesses C_{2v} (C_{2h}) symmetry for odd (even) n . We now discuss the vibrational properties of the chain.

To understand the LVMs of the donors, we first calculate the long wavelength modes of an infinite periodic O -2NN chain. The two IR-active modes lie at 564 and 814 cm^{-1} in Si and 323, 625 cm^{-1} in Ge. The 814 cm^{-1} is shown in Fig. 3(b) and clearly induces a dipole moment along $[001]$. The 564 cm^{-1} mode involves very little movement of oxygen atoms, and is localised to the Si atoms above and below the core whose bonds are compressed by the $[001]$ stress. This has a dipole moment along $[1\bar{1}0]$, and orthogonal to the chain. Thus, the simple periodic chain model explains why only a few oxygen modes can be detected in each donor, as only transverse long wavelength modes are IR-active.

We now consider the oxygen related modes arising from the ends of the chain [Fig. 3(c)]. The highest frequency modes, evaluated from the dynamical matrices of the end-O atoms, are given in Table 1. There is a 11 : 12 : 6 cm^{-1} increase with N in excellent agreement with the observed increases of 13 : 11 : 7 cm^{-1} for TDD(1), TDD(2), TDD(3) and TDD(4). For Ge, the calculated increments are 9 : 8 : 7 cm^{-1} compared with 5 : 4 : 3 cm^{-1} observed for TDD(1), TDD(2), TDD(3) and TDD(4). Thus, the model accounts for the shift in the high frequency mode with N .

We now turn to the effect of a 50–50 mixture of ^{16}O and ^{18}O . We consider O_7 -2NN and plot in Fig. 4 the calculated relative intensities of the local modes. We note that the end-mode at 944 cm^{-1} does not split in agreement with the data. This is because the displacement of the atoms shown in Fig. 3(c) is localised to the end O -1NN atom. However, in contrast with this, the

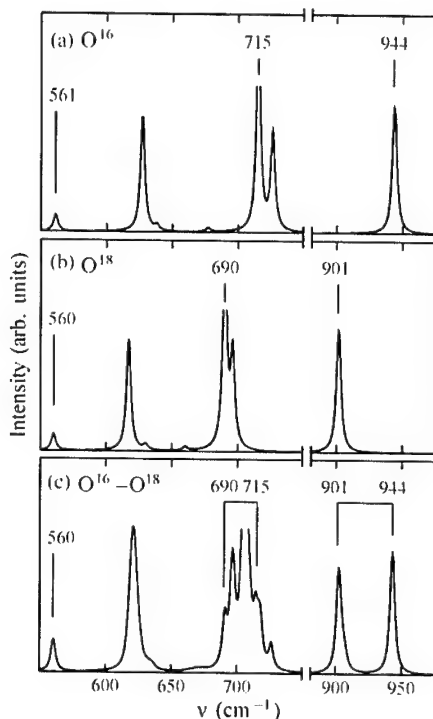

Fig. 4. Calculated IR-intensities of the modes for O_7 -2NN, broadened with Lorentzian functions by 4 cm^{-1} , and evaluated as described above. ^{16}O and ^{18}O spectra are shown in (a) and (b), respectively, whereas the 27 combinations for a 50–50 ^{16}O – ^{18}O mixture are depicted in (c).

mode around 715 cm^{-1} due to the O -2NN core splits in the mixed case [Fig. 4(c)], again in agreement with the data. This reflects its chain origin illustrated in Fig. 3(b). The chain related 560 cm^{-1} Si mode is quite insensitive to O -substitution consistent with an assignment to the observed 580 cm^{-1} band. It is also important to note that the calculated $^{16}\text{O}/^{18}\text{O}$ ratios for the 715 and 944 cm^{-1} modes are 1.036 and 1.046, in good agreement with the observations. Fig. 4(a) also shows that other modes around 726 and 627 cm^{-1} in Si are expected to be IR-active but have not yet been detected.

In the case of Ge, both the end-mode at 748 cm^{-1} and the chain mode at 571 cm^{-1} (^{16}O) are, however, split in the mixed isotopic case, again in agreement with the data. The different behaviour of the end-mode from that

in Si is striking and originates from the closeness in the Ge–O–Ge angles at the ends and middle of the chain when compared with Si. This can be compared with the $\sim 140^\circ$ Ge–O–Ge and $\sim 160^\circ$ Si–O–Si angles for interstitial oxygen [19].

Abstract

Infrared absorption spectra of polyhedral and platelet oxygen precipitates are analyzed using a modified Day–Thorpe approach (J. Phys.: Condens. Matter 11 (1999) 2551). The aspect ratio has been determined by TEM measurements. The reduced spectral function and the stoichiometry are extracted from the absorption spectra and the concentration of precipitated interstitial oxygen. One set of spectra reveal a Fröhlich frequency around 1100 cm^{-1} and another around $1110\text{--}1120\text{ cm}^{-1}$. It is shown that the shift in the Fröhlich frequency is not due to a different stoichiometry, but due to the detailed structure in the reduced spectral function. The oxygen precipitates consist of SiO_2 with $\gamma \approx 1.1\text{--}1.2 \pm 0.1$.

1. Introduction

Oxygen is one of the dominant impurities in Czochralski grown crystalline silicon (Cz). Depending on the thermal treatment oxygen precipitates (SiO_2) with different morphology are formed in Cz silicon [1]. In the literature different values of γ have been reported, ranging from 0.95 to 2 [2–4]. The precise phase, however, has an impact on the precipitate growth kinetics and thus on the interstitial oxygen depletion from the bulk [2]. Therefore, the identification of this phase is highly desirable.

The infrared absorption spectra can be reconstructed using an effective medium theory [3,5–7], only requiring the dielectric functions of the medium and the particles, the volume fractions and the aspect ratio. However, in the former approach [3,4] the analysis depends almost

entirely on the availability of dielectric functions of SiO_2 , which limits the certainty of the statements.

It is assumed that the SiO_2 precipitates consist of two phases [4]: amorphous silicon and amorphous SiO_2 . The effective dielectric function of a composite depends both on the geometry of the composite and on the dielectric functions of the components. The geometrical information can be summarized in the Bergman–Milton (BM) spectral density function [8,9], which is independent of the material parameters. If the spectral function can be extracted from experimental absorption spectra, the volume fractions of the components can be easily obtained, and thus the γ in SiO_2 . Day and Thorpe [10] showed that the spectral functions can be extracted from reflectance data if known properties of the spectral function are incorporated as constraints in the optimization problem. We will make use of their algorithm, but add more constraints, which will allow to obtain the spectral functions and volume fractions in the case of the SiO_2 precipitates in silicon.

2. Experimental

The investigated Si specimens contained an initial interstitial oxygen concentration between 7.5 and $10.2 \times 10^{17} \text{ cm}^{-3}$ (Table 1) and are divided into four groups of annealing schemes.

The first set of samples (i) received a nucleation step (800°C in N_2 for 24 h) followed by a high-temperature step (3 h, 1100°C in wet oxygen) (samples SD1 and SD2). The second group (ii) received a series of pretreatment followed by a high-temperature step at 1000°C for a duration ranging from 1 to 32 h (samples SD3 and SD4). The third group (iii) received nucleation step (16 h at 500°C), followed by a stabilization step (16 h at 800°C) and a growth step (8 h at 1050°C) (sample SD5) [11]. The last group (iv) received a very long treatment at 750°C in N_2 ambient for 265 h in order to produce a high density of stable oxide precipitate nuclei. This was followed by a treatment at 1050°C in Ar for 2 h (samples SD6, S1 and S2) [4]. The oxygen content before the annealing treatments was determined by measuring the height of the absorption peak at 1107 cm^{-1} at 300 K, using the IOC88 standard calibration conversion factor ($3.14 \times 10^{17} \text{ cm}^{-2}$) [12]. The interstitial oxygen remaining after annealing was determined at 6 K by measuring the height of the 1206 cm^{-1} peak [13]. In this way, the broad absorption peak at 300 K belonging to the remaining interstitial oxygen could be removed by subtracting a scaled 1107 cm^{-1} absorption peak from the experimental spectrum, leaving the spectrum of precipitated oxygen only [4]. Transmission electron microscopy (TEM) observations were performed at 200 keV along the $[001]$ direction (plan view) and along the $[011]$ direction (cross-section) on two samples (SD6 and S2).

3. Theory, model and simulations

The dielectric function can be obtained by assuming that the particles themselves are composites of inert

amorphous silicon (a-Si) ($\epsilon_m = 11.7$) and thermal oxidized SiO_2 [14] (t- SiO_2), and thus can be approximated with an effective medium theory. Because representation of the dielectric function of SiO_2 with damped harmonic oscillators is a rather crude approximation for amorphous solids [4,15] the dielectric function of t- SiO_2 was re-extracted using a Gaussian broadened harmonic oscillator model [15,16].

In the BM spectral representation the effective dielectric function of a two component material is given by [10]:

$$\epsilon_p = \epsilon_{pm} \left(1 - \frac{\sigma_{pp}}{s_{pm}} - \int_0^1 \frac{g(x)}{x(s_{pm} - x)} dx \right) \quad (1)$$

with ϵ_p , ϵ_{pm} , ϵ_{pp} the effective dielectric function of the composite, the dielectric function of the host (a-Si) and of the inclusion in the composite (t- SiO_2), σ_{pp} the weight of the delta function of the spectral function at the origin, $g(x)$ is the reduced spectral function [10], and $s_{pm} = [1 - \epsilon_{pp}/\epsilon_{pm}]^{-1}$. The reduced spectral function has some interesting properties [10]. $g(x)$ is zero at $x = 0$ and 1, and $g(x) \geq 0$ on the interval $[0,1]$. Furthermore the zeroth moment gives the volume fraction of the inclusion p_{pp} :

$$p_{pp} = \sigma_{pp} + \int_0^1 \frac{g(x)}{x} dx \quad (2)$$

and for an isotropic material the first moment satisfies: $\mu_1 = \int_0^1 g(x) dx = p_{pp}(1 - p_{pp})/3$.

The absorption spectrum for oxide particles in a silicon matrix is given by [3,6]: $\alpha = 2\pi\nu \text{Im}(\epsilon_{\text{eff}})/\text{Re}(\epsilon_{\text{eff}}^2)$, with ν the wave number (in cm^{-1}), and $\epsilon_{\text{eff}}(\nu, f_s, f_d, \epsilon_m, \epsilon_p, y)$ the effective dielectric function [16] according to the continuum theory of Genzel and Martin [7] for spherical and oblate spheroidal [3,6] particles, where f_s and f_d are the volume fractions of polyhedral and platelet precipitates, ϵ_m and ϵ_p the dielectric function of the silicon matrix and the unknown effective dielectric function for the SiO_y particles (see Eq. (1)), and y is the aspect ratio. The resonance wave number is given by the Fröhlich wave number (ν_s) for a sphere and by the longitudinal optical (LO) wave number (ν_{LO}) for a perfect disk, while for an oblate spheroid the resonance wave number (ν_d) lies between ν_s and ν_{LO} , depending on y . The absorption spectrum of the oxide precipitates is located in the reststrahlen region (the region between transverse optical wave number ν_{TO} and ν_{LO}) of t- SiO_2 . In the case of SiO_y particles the medium consists of a rather inert medium (a-Si) and a medium with a strong resonance in the reststrahlen region. These two conditions should allow the extraction of the reduced spectral function.

The spectral functions are extracted by minimizing the following chi-squared function $\chi^2 = \chi_x^2 + \chi_c^2$, where $\chi_x^2 = \sum |\alpha(\nu_i) - \alpha(\nu_i, \sigma_{pp}, g(x), f_s, f_d, y)|^2$ and $g(x)$

Table 1
Oxygen concentration before and after heat treatments

Sample name	[O _i] (initial) (10^{17} cm^{-3})	[O _i] (final) (10^{17} cm^{-3})

Fig. 1. Application of the optimization procedure to experimental absorption spectrum (set I). (a) Absorption spectrum of sample SD6 (solid line) and the best fit (dashed curve). (b) Average reduced spectral function for the samples of set I, with $\sigma_{pp} = 0.49 \pm 0.03$.

approximated as a histogram with 64 bins.¹ As the heart of the problem is an inhomogeneous Fredholm equation of the first kind (Eq. (1)), the problem will be ill-conditioned [10]. The standard strategy to tackle such a problem is to insert a priori knowledge into the chi-squared equations by means of a set of constraints (χ_c^2):

$$\chi_c^2 = \lambda_1 (\mu_1 - \frac{1}{3}p_{pp}(1 - p_{pp}))^2 + \lambda_4 (\nabla g(x))^2 + \lambda_2 (\Delta[O_i] - [O]_{pp})^2 + \lambda_3 [\Delta v_s^2 + v_d^2], \quad (3)$$

where $\Delta[O_i]$ is the disappeared interstitial oxygen, $[O]_{pp} = (f_s + f_d)p_{pp}C_{SiO_2}$ is the concentration of oxygen in the precipitates, and $C_{SiO_2} (= 4.6 \times 10^{22} \text{ cm}^{-3})$ is the oxygen in SiO_2 . The solution has to satisfy the first-moment relation (first term in Eq. (3)) [10]. The second term is a smoothing term, to prevent wild oscillations in $g(x)$ [10]. The third term states that all the disappeared interstitial oxygen ($\Delta[O_i]$) is in the precipitates ($[O]_{pp}$). The last term gives the differences between the experimental and the simulated v_s and v_d , as those are closely related with v_{TO} and v_{LO} , which in turn determine the dielectric function [5]. Tests on simulated spectra demonstrated that the algorithm is capable of extracting the volume fractions f_s, f_d, p_{pp} accurately and $g(x)$ with a modest accuracy, while the estimates on γ were somewhat underestimated [16]. The accurate determination of p_{pp} allows to determine the stoichiometry.

4. Results and discussion

The samples can be divided in two sets (Table 1). The first set of samples (set I, SD1–SD6) reveals two resonance wave numbers in the absorption spectra around 1115–1120 cm^{-1} and 1215–1225 cm^{-1} , traditionally assigned to polyhedral and platelet precipitates, respectively [1,6]. The second set (set II, S1–S2) consists of samples with only one resonance wave number around 1100 cm^{-1} , due to polyhedral precipitates [1]. As this resonance wave number is clearly shifted with regard to the samples of set I, one might expect that this is due to a different phase or to a different geometry of the medium.

One sample from set I (SD6) and one from set II (S2) were investigated with TEM. The first sample contained polyhedral and platelets, the latter having an aspect ratio around 0.04 ± 0.02 . No platelet precipitates were observed in the second (S2) sample, as expected.

The algorithm is applied on the two sets of samples. For set I a volume fraction (p_{pp}) of 0.71 ± 0.04 and for set II a slightly lower value of 0.66 ± 0.03 were obtained. This is equivalent with SiO_{γ} , with $\gamma = 1.20 \pm 0.10$ and 1.08 ± 0.07 , respectively. The difference in p_{pp} for the two sets is less than 7%, which is not significant, and their 95% confidence regions overlap. Hence, the shift of the Fröhlich wave number from 1110 to 1100 cm^{-1} is not related to a change in volume fraction but is rather due to the detailed picture of $g(x)$, and thus due to a slightly different geometrical structure of the composite. For the samples of set I $g(x)$ has a maximum around $x \approx 0.55$ (Fig. 1(b)), while for the samples of set II the maximum is located around $x \approx 0.3–0.4$ (Fig. 2(b)). The error bars

¹Contrary to Day and Thorpe [10], we do not use a symmetric effective dielectric function.

Fig. 2. Application of the optimization procedure to experimental absorption spectrum (set II). (a) Absorption spectrum of sample S2 (solid line), and the best fit (dashed curve). (b) Average reduced spectral function for the samples of set II., with $\sigma_{pp} = 0.43 \pm 0.02$.

of $g(x)$ for set II are somewhat larger, because the corresponding $g(x)$ has a rather narrow peak, which is much harder to resolve.

In Fig. 1(a) the absorption spectrum of sample SD6, together with the best fit is given. The obtained aspect ratio is 0.02, which is at the lower border of the error interval determined from the TEM measurements. In Fig. 2(a) an example of set II is given. In both cases the fits to the absorption spectra are good. Deviations can be due to the uncertainty on the dielectric function and to the use of an oscillator model to approximate the dielectric function. Generally, the constraints on the oxygen concentration (third term in Eq. (3)) agreed to within 15%, while the constraint on the first moment (first term in Eq. (3)) agreed to within 25%.

5. Conclusions

The modified Day–Thorpe algorithm has been adapted to the case of absorption spectra of SiO_2 precipitates in silicon and was more severely constrained. This permitted to determine the volume fraction of SiO_2 in the precipitates quite accurately. Also the reduced spectral functions for two sets of specimens with different Fröhlich wave number could be obtained with a moderate accuracy. The shift in the Fröhlich wave numbers is related to a different geometrical structure, of which the reduced spectral function is the emanation. The precipitates consist of SiO_2 with $\gamma = 1.1$ – 1.2 . Regarding the wide range of experimental situations, the latter result seems to be quite general.

Effect of oxygen on exciton transitions in silicon

A.N. Safonov, Gordon Davies*

Physics Department, King's College London, Strand, London WC2R 2LS, UK

Abstract

The spectral line shape of the α_1 no-phonon line of the exciton bound to phosphorus donors in silicon is asymmetric and it broadens rapidly with increasing oxygen concentration. We show that these effects can be accounted for by assuming that a neutral oxygen atom has a short-range potential, decreasing sufficiently rapidly with distance that the first-order effect on the exciton energy level is proportional to the exciton density on the oxygen atom. Different combinations of oxygen atoms around the phosphorous centers produce a variety of frequency shifts resulting in the inhomogeneous broadening of the α_1 line. Assuming that oxygen atoms are randomly distributed relative to the phosphorus donors, the profile of the α_1 line can be simulated and the strength of the short-range potential determined. © 2001 Elsevier Science B.V. 1. Introduction

Optical transitions in semiconductors are often inhomogeneously broadened by crystal imperfections. For example, point defects, dislocations and charge centers produce randomly distributed strain fields and electric fields that can affect the frequency of optical transitions. The line shapes of the transitions then depend on the statistical distributions of the fields at the optical centers. Consequently, line shapes can be used to monitor changes in the relative distributions of the defect and optical centers, for example during annealing treatments [1], and, as in this report, they reveal the nature of the perturbation produced by individual defects.

This paper is concerned with the effect of oxygen, one of the most common impurities in silicon, on localized exciton states bound to phosphorus donors. A substitutional phosphorus atom in silicon forms an effective-mass donor. The electron states are derived from the six equivalent conduction-band minima, which lie along

$\mathbf{k} \parallel \langle 001 \rangle$ directions. At the T_d site of the P atom, these six states transform as A_1 , E and T_2 states, with the orbital singlet state A_1 lowest [2]. An exciton may be captured by the center, with a small binding energy (4.7 meV; Ref. [3]). The two electrons now trapped at the P atom spin-pair in the A_1 state, and the hole orbits in a state derived from the Γ_8 valence-band maximum. Luminescence resulting from the recombination of the hole with one of the electrons has been well-studied, including its response to externally applied stresses [4]. We concentrate here on the sharpest spectral line, the so-called α_1 line, whose width can be less than 1 μeV in isotopically pure Si [5]. In pure natural-abundance Si the width is 5 μeV , increasing with oxygen content to 100 μeV at $[\text{O}] \sim 10^{18} \text{ cm}^{-3}$ [6]. At the same time, the line shape becomes highly asymmetric with a tail towards higher photon energies (Fig. 1). The broadening of the α_1 transition has been attributed to the spatial fluctuations of the band gap produced by the strain fields of the oxygen atoms. This effect can be calculated, since both the responses to strains of the α_1 line [4] and the strains produced by the oxygen are known [7]. We show below that the resulting line shape would be a symmetric doublet, very different from that observed (Fig. 2). Instead, we will show that the observed line

Fig. 1. Points show the measured spectrum of the α_1 transition in samples with an oxygen concentration of (a) $3 \times 10^{16} \text{ cm}^{-3}$, (b) $7 \times 10^{16} \text{ cm}^{-3}$, and (c) $3 \times 10^{17} \text{ cm}^{-3}$. The lines are the calculated spectra assuming a short-range potential at the oxygen atoms.

Fig. 2. Points show the measured spectrum of the α_1 transition in a sample with an oxygen concentration of $3 \times 10^{17} \text{ cm}^{-3}$. The line is calculated using strain broadening theory.

width and shape can be accounted for by assuming that the oxygen atoms are randomly distributed and that a neutral oxygen atom has a short-range potential, decreasing sufficiently rapidly with distance that its

first-order effect on the exciton energy level is proportional to the density of the exciton on the oxygen atom. Different combinations of oxygen atoms around the phosphorous centers produce a variety of frequency shifts, resulting in the inhomogeneous broadening of the α_1 line.

2. Experimental details

Silicon grown by the Czochralski process, using a crucible made of silica, contains a supersaturated concentration of oxygen. During a slow cool-down, or any post-growth heating, the oxygen atoms can become mobile and begin to precipitate. The samples used here had been specially processed for the experiments on isolated oxygen atoms and any small aggregates of oxygen had been thermally dissociated.

Photoluminescence spectra were measured using an Ar^+ laser, running at an output power of 100–200 mW, with the samples immersed in liquid helium at 4.2 K. The luminescence was measured at a resolution of $5 \mu\text{eV}$ using a Bomem DA8 Fourier transform spectrometer fitted with a North Coast Ge detector. To avoid experimentally-induced strain-broadening, the samples were tied to the sample holder using Teflon tape, and the spectra were measured at points remote from the tape.

3. Results and discussion

Interstitial oxygen is positioned between two silicon neighbors, with a Si–O–Si angle of 160° and Si–O bond length $\sim 0.16 \text{ nm}$ [8]. Since the Si–Si bond has length of 0.234 nm , an expansion of the silicon lattice is expected, and its volume increases at the rate of

$$\Delta V/V = 1.3 \times 10^{-23} [\text{O}], \quad (1)$$

where $[\text{O}]$ is the oxygen concentration in cm^{-3} [7]. The corresponding factor for substitutional carbon is $-1.95 \times 10^{-23} \text{ cm}^{-3}$ [9].

Within the elastic approximation the lattice displacement u at the distance r from a point defect in an infinite crystal would be $u = rA/r^3$, where A is a lattice mismatch parameter. The corresponding strain tensor e_{ij} at the point (r_1, r_2, r_3) a distance r from the oxygen atom is given by

$$e_{ij} = A/r^3 (\delta_{ij} - 3r_i r_j / r^2), \quad (2)$$

where $\delta_{ij} = 1$ if $i = j$ and is otherwise 0 [10]. It follows that the hydrostatic component of this field is equal to zero at any non-zero r . However, at $r = 0$ there is a local change of the volume occupied by the oxygen atom, with a magnitude $\Delta V_c = 4\pi A$ for each oxygen atom. In addition, there is a long-range contribution to the volume change associated with

the image forces at the surface of a finite crystal. This term gives a further dilatation for each oxygen atom of $\Delta V_s = 8\pi A(1 - 2\sigma)/(1 + \sigma)$, where σ is Poisson's ratio for an isotropic crystal; we take $\sigma = 0.22$ since $\langle 001 \rangle$ strains give the largest perturbation. The total volume change per oxygen atom is then

$$\Delta V = \Delta V_c + \Delta V_s = 12\pi A \frac{(1 - \sigma)}{(1 + \sigma)}, \quad (3)$$

allowing A to be found from Eq. (1) since the oxygen concentration is measurable [11]. Consequently, the strains e_{ij} are known from Eq. (1)

The effect of randomly distributed carbon impurities on the α_1 transition has been considered in Ref. [12]. It was shown that the presence of the inhomogeneous strain field produces not only a broadening but also a splitting of α_1 into two lines. Strain-broadening theory accurately fitted the data. Application of the same theory to the present samples, with oxygen as the strain source, gives the result in Fig. 2, substantially sharper than the experimental line shape, and a symmetric doublet rather than asymmetric singlet observed. It is clear that inhomogeneous strains cannot account for the oxygen broadening of the line.

To explain the effect of oxygen on the α_1 transition we shall consider a localized perturbation produced by each oxygen atom. We shall assume that the neutral O atom has a short-range potential located within a radius R_0 . Its effect on the exciton state is then proportional to the exciton density at the location of O atom. We assume that the exciton distribution can be described by a wavefunction of the form

$$\psi = \frac{1}{\sqrt{\pi R_b^3}} \exp\left(-\frac{r}{R_b}\right). \quad (4)$$

When R_0 is small in comparison with the 'Bohr radius' R_b , the energy shift of the exciton state is, in the first order,

$$\Delta h\nu = B \exp\left(-\frac{2r}{R_b}\right), \quad (5)$$

where B is an interaction parameter determined by the strength of the oxygen potential.

Using Eq. (5) and assuming that the oxygen atoms are randomly distributed in the silicon lattice, we can calculate the profile of the α_1 line. The solid lines on Fig. 1 show the simulated spectra obtained for oxygen concentrations (a) $3 \times 10^{16} \text{ cm}^{-3}$, (b) $7 \times 10^{16} \text{ cm}^{-3}$, and (c) $3 \times 10^{17} \text{ cm}^{-3}$, with $B = 0.8 \text{ meV}$ and $R_b = 2.2 \text{ nm}$. The calculated spectra have also been broadened by the random strain fields of the oxygen, as described above, and, to allow for broadening effects common to all the samples, the spectra have been broadened with the use of the line shape that corresponds to the experimental shape of α_1 at low [O] (0.2 part of Lorentzian and 0.8

part of Gaussian, both having half-width of $10 \mu\text{eV}$). The calculated spectra are in good agreement with the experimental results which are shown in Fig. 1 by dots.

In the model, the parameter R_b determines the extent of the volume sampled by the bound exciton, and so controls primarily the extent of the asymmetric tail. Its value is similar to the 'effective excitonic radius' quoted as $\sim 3.5 \text{ nm}$ [13]. The parameter B scales the width of the distribution. The value of B is consistent with the first-order perturbation of the excited state $\psi(r)$ by a perturbing potential $V(r)$ which is described by a constant potential V_0 located in the small volume R_0^3 occupied by the oxygen atom

$$\Delta E = \int d\mathbf{r} V(r) |\psi(r)|^2 = \frac{V_0 R_0^3}{\pi R_b^3} \exp(-2r/R_b).$$

Comparison with Eq. (5) gives $V_0 = B\pi R_b^3/R_0^3$, and hence a plausible value of $V_0 \sim 2.4 \text{ eV}$ if R_0 is an interatomic spacing.

We have shown that oxygen can increase the energy of the transition through the effect of its short-range (chemical) potential. The exciton bound to phosphorus is a simple case since its wave function will plausibly decrease slowly in space in the form of Eq. (4) and so its detailed structure is unimportant. The same mechanism could produce considerably larger upshifts at more tightly bound centres.

Disturbance of oxygen by isovalent impurity atoms in silicon

L.I. Khirunenکو*, V.A. Zasuha, Yu.V. Pomozov, M.G. Sosnin

Institute of Physics, National Academy of Sciences of Ukraine, Prospect Nauki 46, 03028 Kyiv, Ukraine

Abstract

The diagram of electronic levels of A–Si–O–Si–A clusters (where A is carbon, germanium, tin or lead), has been obtained by group-theoretical analysis and molecular orbitals approaches. Three possible forms of Si substitution by isovalent impurity atoms are discussed. A linear A–Si–O–Si–A cluster and the clusters with A located in the second sphere relative to an oxygen atom with formation of a planar trans-configuration and a nonplanar cis-configuration were considered. It has been shown, that all these forms of Si substitution by isovalent impurity atoms lead to the decrease of the force constants and frequencies of local vibrations of Si–O–Si, respectively. © 2001 Elsevier Science B.V. Keywords: Silicon; Oxygen; Isovalent impurity; Disturbance

1. Introduction

Oxygen (O) is known to be the main and most intensively studied impurity in CZ-grown Si. It is one of the most active impurities in defect formation processes in Si. In recent years, the investigation of the properties of Si doped with isovalent impurities (IVI) has become a matter of considerable interest. It has been found that IVI in Si influence the diffusion of O and its precipitation at heat treatments, the formation processes of radiation defects. However, the mechanism of interaction between O and IVI atoms has not been adequately studied up to date.

The study of O properties in as-grown materials is interesting first of all. It is known that the doping of Si by IVI atoms leads to an appearance of the additional local modes in the frequency region corresponding to ν_3 vibrational mode of O [1–3] (Fig. 1). As it is seen from Fig. 1, for all IVI, additional bands appear on the low-frequency side relative to the band characteristic of Si, independent of the sign of the strain produced by IVI. In Refs. [1–3], additional bands observed were ascribed to the ν_3 vibrational mode of interstitial O disturbed

by IVI atom located in the second, third or fourth neighbouring site.

In this work, it is shown that an additional structure in the absorption spectrum of oxygen in IVI-doped silicon can appear due to the nonequivalent arrangement of IVI atom in the nearest Si–O–Si environment (in the second sphere relative to an oxygen atom).

2. Results and discussion

Oxygen is known to form in the Si lattice a Si–O–Si (Si_2O) quasimolecule oriented along the axis [1 1 1] [4–6]. Quasimolecule has D_{3d} symmetry and forms a $\text{Si}_3\text{--Si--O--Si--Si}_3$ cluster in Si. To explain the peculiarities observed in the absorption spectrum of O in IVI-doped Si, let us choose the following model. Si is known to have a tetrahedrally coordinated diamond structure, according to which the Si atoms are arranged pair-wise along the [1 1 1] axis with vacant lattice sites between them and form a $\bullet\text{--Si--Si--}\bullet\text{--Si--Si--}\bullet$ chain (where the points denote the vacant lattice sites) [7,8]. These vacant lattice sites are possible places of the localization of IVI atoms. Consider the linear cluster A–Si–O–Si–A along the [1 1 1] axis, which is shown in Fig. 2a. First, consider the electronic structure of the Si_2O quasimolecule and then analyse the effect of C, Ge, Sn and Pb atoms on it.

Absorption bands of interstitial oxygen in Si and Si doped with Ge, Sn and C measured at 4.2 K with resolution 0.25 cm^{-1} . $N_{\text{Ge}} \approx 1.1 \times 10^{20} \text{ cm}^{-3}$; $N_{\text{Sn}} \approx 2 \times 10^{19} \text{ cm}^{-3}$; $N_{\text{C}} \approx 8 \times 10^{17} \text{ cm}^{-3}$.

Fig. 2. Linear cluster A-Si-O-Si-A (a) and clusters with planar trans- (b) and nonplanar (c) cis-structures.

The energies of the 3s and 3p levels of the Si atom are $-14,965$ and -7755 eV [9] and the ones of the 2s and 2p levels of the O atom are $-34,078$ and $-17,238 \text{ eV}$ [10]. The energy values of the levels with opposite signs are known to correspond to ionization potentials. Thus, the 2s and 2p levels of the O atom lie below the 3s and 3p levels of the Si atom. The ionization energies and potentials of the *ns* and *np* levels of the Ge, Sn and Pb atoms are known to have lower values as compared with the Si atom and higher values for the C atom. This is accounted for by the fact that the position of the *ns* and *np* levels become higher when the principal quantum number increases in the order C, Si, Ge, Sn, Pb. Let us analyse the electronic structure of cluster A-Si-O-Si-A by the theoretical group analysis [11] and molecular orbital methods [12,13]. Table 1 gives a classification.

Table 1

Classification of AO's of oxygen atom and GO's of Si, C, Ge, Sn and Pb atoms in $\text{Si}_1\text{-O-Si}_2$ quasimolecule and $\text{A}_3\text{-Si}_1\text{-O-Si}_2\text{-A}_4$ cluster

$\text{H}\Pi_j$	O	$\Gamma\text{O}, \varphi_{ij}$	
		$\text{Si}_1\text{-Si}_2$	$\text{A}_3\text{-A}_4$
$\text{A}_{1g}(\text{E}_g^+)$	s	$(s_1 + s_2)/\sqrt{2}$ $(p_{z1} - p_{z2})/\sqrt{2}$	$(s_3 + s_4)/\sqrt{2}$ $(p_{z3} - p_{z4})/\sqrt{2}$
$\text{A}_{2u}(\Sigma_u^+)$	p_z	$(s_1 - s_2)/\sqrt{2}$ $(p_{z1} + p_{z2})/\sqrt{2}$	$(s_3 - s_4)/\sqrt{2}$ $(p_{z3} + p_{z4})/\sqrt{2}$
$\text{E}_g(\Pi_g)$		$(p_{x1} - p_{x2})/\sqrt{2}$ $(p_{y1} - p_{y2})/\sqrt{2}$	$(p_{x3} - p_{x4})/\sqrt{2}$ $(p_{y3} - p_{y4})/\sqrt{2}$
$\text{E}_u(\Pi_u)$	p_x p_y	$(p_{x1} + p_{x2})/\sqrt{2}$ $(p_{y1} + p_{y2})/\sqrt{2}$	$(p_{x3} + p_{x4})/\sqrt{2}$ $(p_{y3} + p_{y4})/\sqrt{2}$

obtained by the theoretical group analysis method, of the atomic orbitals (AO) of the O atom and group orbitals (GO) of Si and A atoms in the cluster $\text{A}_3\text{-Si}_1\text{-O-Si}_2\text{-A}_4$ with D_{3d} symmetry (in the case of the cluster in the crystal) and $\text{D}_{\infty h}$ symmetry (for isolated state) for a linear cluster. In this case, it was taken into account that in passing from group $\text{D}_{\infty h}$ to D_{3d} , the irreducible representations (IR) transform as follows [11]: $\Sigma_g^+ \rightarrow \text{A}_{1g}$, $\Sigma_g^- \rightarrow \text{A}_{2g}$, $\Sigma_u^+ \rightarrow \text{A}_{2u}$, $\Sigma_u^- \rightarrow \text{A}_{1u}$, $\Pi_g \rightarrow \text{E}_g$, $\Pi_u \rightarrow \text{E}_u$. The GO's are formed by the effects of the projection operator $\sum_R \chi^j(R) T_R$ on s and p AO, where T_R and $\chi^j(R)$ are the transformation operator and the character of IR *j* (A_{1g} , A_{2g} , E_u , A_{2u} , Π_g , etc.), respectively, to which the symmetry operation *R* corresponds. It is known [13] that symmetry operations transform the p_x , p_y , p_z AO equivalently to the *x*, *y* and *z* axes of the coordinate system.

According to the variational perturbation theory [14], the ε_{ij} energy levels and, corresponding to them, the molecular orbitals Ψ_{ij} of the quasimolecule and cluster are expressed as

$$\varepsilon_{ij} = F_{ii,j} - \sum_{n \neq i} (F_{in,j} - F_{ii,j} S_{in,j})^2 / (F_{nn,j} - F_{ii,j}), \quad (1)$$

$$\Psi_{ij} = N_{ij} \left\{ \varphi_{ij} - \sum_{n \neq i} [(F_{in,j} - F_{ii,j} S_{in,j}) / (F_{nn,j} - F_{ii,j})] \varphi_{nj} \right\}, \quad (2)$$

$$N_{ij} = \left\{ 1 + \sum_{n \neq i} [(F_{in,j} - F_{ii,j} S_{in,j})^2 (F_{nn,j} - F_{ii,j})^{-2} - 2 S_{in,j} (F_{in,j} - F_{ii,j} S_{in,j}) (F_{nn,j} - F_{ii,j})^{-1}] \right\}^{-1/2}, \quad (3)$$

where *i* is the level number, *j* is the IR of the symmetry group, $F_{in,j}$ and $S_{in,j}$ are the matrix elements of the

Hartree-Fock operator \hat{F} and overlap integrals, and N_{ij} are normalization constants, which were obtained with the aid of the condition of normalization $\langle \Psi_{ij} | \Psi_{ij} \rangle = 1$. The energy of the two-fold degenerate level ε_{1E_g} to which the GO's of the Si₁ and Si₂ atoms (nonbonding MO's) correspond, is

$$\varepsilon_{1E_g} = \langle E_g | \hat{F} | E_g \rangle \approx \varepsilon_{3pSi} = -I_{3pSi}, \quad (4)$$

where ε_{3pSi} and I_{3pSi} are the ionization energy and potential of the 3p level of Si atom.

Fig. 3a shows the level diagrams obtained for the Si₂O quasimolecule. The electronic structure of complex systems, to which the A–Si–O–Si–A cluster belongs, can be constructed only by the method of linear combination of molecular orbitals (LCMO) [12,13] of interacting subsystems (fragments)—MO's of the Si₂O and GO's of A atoms (see Table 1 and Fig. 2a). A diagram of the A–Si–O–Si–A cluster obtained this way is shown in Fig. 3b. It follows from the diagram (Fig. 3a) and the formulae (1), (2) that the 1A_{2g}, 2A_{1g}, 3A_{1g} MO's of the Si₂O are nonbonding since the differences in the ionization potentials between the 2s level of the O atom and the 3s and 3p levels of the Si atom are large and are 19.113 and 26.323 eV. The 1A_{2g} MO is AO 2s of the O atom, and 2A_{1g}, 3A_{1g}, are linear combinations of GO's composed of AO 3s and 3p of Si atoms with opposite signs. The 1A_{2u}, 1E_u and 3A_{2u} MO's are of bonding and antibonding characters with the localization of electron

density inside and outside the Si–O–Si bond, respectively. The 2A_{2u} MO is weakly antibonding since the antibonding by the contribution of the AO 2p of the O atom is partially compensated by the contribution of the GO of Si atoms, which is composed of AO 3p_z. As it was already mentioned, the 1E_g MO's are nonbonding on symmetry and are GO's composed of the AO 3p_x, 3p_y of Si atoms. The 1A_{1g}, 1A_{2u}, 1E_u MO's make a very small contribution to the formation of bonds between Si₂O and A atoms and Si atoms of the next environment spheres because their overlap integrals have the same GO symmetry, and hence, the matrix elements of the \hat{F} operator are negligible. The 2A_{1g}, 2A_{2u}, 1E_g, 3A_{1g}, 2E_u, 2A_{2u} MO's of the Si₂O contribute to the formation of their bonds since the electron densities of these MO's are concentrated on the Si atoms, which ensure their overlaps, and the matrix elements of the \hat{F} operator with the above GO's are nonzero. Thus, the 2A_{1g}, 2A_{2u}, 1E_g, 3A_{1g}, 2E_u, 3A_{2u} MO's are delocalized on the A and Si atoms of the next environment spheres of the Si₂O in crystal, and the 1A_{1g}, 1A_{2u}, 1E_u MO's are localized on the O atom and Si–O bonds, correspondingly. The latter MO's determine the locality (characteristicity) of the bonds of Si₂O and lead to the appearance of characteristic vibrational modes of the Si₂O in the absorption spectra. The LCMO method [12,13], which was employed by us in the study, showed that the bond between the Si₂O and the A atoms in the A–Si–O–Si–A cluster are formed by its 2A_{1g}, 2A_{2u}, 1E_g, 3A_{1g}, 2E_u, 3A_{2u} MO's and the GO's of the corresponding IR's of two atoms of A.

It follows from the level diagram of the A–Si–O–Si–A cluster shown in Fig. 3b that the bonds in the cluster are realized by the electrons of the 2A_{1g}, 2A_{2u}, 1E_g, 2E_u MO's, and that the 3A_{2u}, 3A_{1g} MO's are of a weak bonding or antibonding nature in accordance with formulae (1) and (2) since the bonding and antibonding contributions partially compensate each other. Since the 2A_{1g}, 2A_{2u} and 1E_g MO's of the Si₂O quasimolecule are nonbonding, their participation in the formation of bonds to the A atoms does not greatly affect the force constants and vibration frequencies of Si₂O. However, the participation of the antibonding 2E_u, 3A_{2u} MO's of Si₂O in the formation of bonds to A impurities weakens the intramolecular bonds of the quasimolecule, and, consequently, its force constants and hence, vibration frequencies decrease.

The possible nature of the shift of the vibrational absorption bands of the Si–O–Si quasimolecule (which are associated with the perturbation by A atoms), which was established for the linear A–Si–O–Si–A cluster, is also characteristic of cluster with planar trans-structure and nonplanar cis-structure, which are produced by the substitution of A atoms for Si atoms in the next environment sphere of quasimolecule as is shown in Figs. 2b and c. Here, as in the case of linear cluster, the force constants and vibration frequencies of the Si₂O

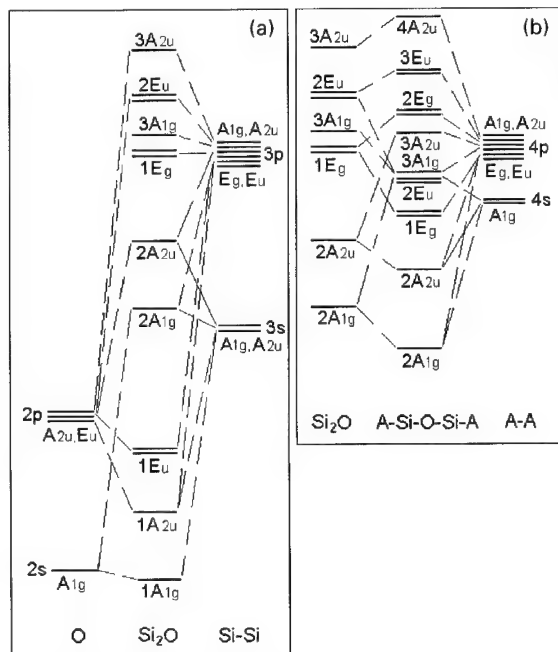

Fig. 3. Levels diagram Si–O–Si quasimolecule and A–Si–O–Si–A (A = C, Ge, Sn, Pb) cluster.

quasimolecule decrease due to the interaction of the antibonding $2E_u$ and $3A_{2u}$ MO's of Si_2O with A atoms. However, when the linear structure changes to the planar trans-structure or nonplanar cis-structure with an angle of 60° between Si–A bonds (Fig. 2c), the fully symmetric and antisymmetric states (Fig. 3b) transform according to the IR's of A_g and A_u of C_i symmetry group and A and B of C_2 symmetry group of the planar trans- and nonplanar cis-structures, respectively. This leads to the removal of the degeneracy of the states E_g and E_u , to the strengthening of the Si–A bonds, weakening of the bonds in the Si_2O and decreasing of the vibration frequencies since the number of the MO's of the Si_2O quasimolecule and GO's of the impurity atoms A, which refer to the same IR, increases. The above effects are more pronounced in the case of nonplanar cis-structure, for which GO's composed of s orbitals of A atoms contribute to interactions with both degenerate states E_g and E_u of the Si_2O quasimolecule and with only one state in the case of planar trans-structure.

Thus, the investigation carried out by the LCMO method show that additional bands can appear in absorption spectra of the Si_2O quasimolecule in silicon due to different forms of substitution of isovalent atoms for Si atoms in the second environment sphere of oxygen.

Abstract

The interstitial carbon–oxygen complex is one of the most prominent defects formed in e-irradiated Cz-Si containing carbon. Stress alignment investigations have shown that the oxygen atom only perturbs the carbon interstitial but the lack of a high frequency oxygen mode has been taken to imply that the oxygen atom is over-coordinated. Local vibrational mode spectroscopy and ab initio modeling are used to investigate the defect. We find new modes whose oxygen isotopic shifts, along with the piezospectroscopic stress-energy tensor support the trivalent model, thus providing evidence for oxygen over-coordination. © 2001 Elsevier Science B.V. 1. Introduction

Low temperature e-irradiation of Si generates mobile Si interstitials which are readily trapped by substitutional carbon defects forming carbon interstitials (C_i). In turn, these are mobile at room temperature and subsequently complex with many impurities including oxygen. The interstitial carbon–oxygen center (C_iO_i) is a product of the latter interaction and is a stable defect with an annealing temperature around 350–450°C [1]. It has been detected by all four principal methods used to characterize defects. Electron paramagnetic resonance (EPR) relates the $C_iO_i^{(+)}$ defect to the G15 signal [2]. Its similarity with the magnetic properties of $C_i^{(+)}$ implies that the C-atom is only slightly affected by oxygen. The defect gives a prominent 0.7896 eV photoluminescent

(PL) signal (C-line) [3], associated with several local mode replicas [1]. Previous Fourier transform infra-red (FTIR) spectroscopic experiments have identified local vibrational modes (LVMs) at 1116, 865, 742, 550 and 529.8 cm⁻¹ [4]. Finally, deep level transient spectroscopy (DLTS) has linked a donor level at $E_v + 0.38$ eV with the defect [5].

Based on stress alignment arguments, the structure shown in Fig. 1a was put forward [2]. On the other hand, as depicted in Fig. 1b, theoretical modeling proposed a strongly affected oxygen atom relative to its normal bond-centered placement. It was then argued that the greater electronegativity of carbon encouraged electron transfer from the dangling bond at the Si_2 atom, leading to an Si_2 –O oxidative bond at the expense of a lone pair orbital on oxygen [6].

Interest in the defect has recently arisen from two fronts: (i) the observation of its reduction by irradiating hydrogenated samples [7,8] and, (ii) the suggestion that

*Corresponding author.

E-mail address: coutinho@excc.ex.ac.uk (J. Coutinho).

the interaction between H and a prominent radiation-induced defect like VO or C_iO_i gives rise to the first member of a shallow donor family (labeled as DN with $N = 1, 2$ and 3) [9,10], with D2 and D3 identified as STD(H)2 and STD(H)3 members of the hydrogen-related shallow thermal donor family [STD(H) N] [11].

Oxygen over-coordination has been a matter of interest, as it is thought to be the origin for donor activity on thermal donors. A comprehensive study of the C_iO_i defect by FTIR and ab initio modeling is presented here, paying special attention to the coordination of the O-atom.

2. Experiments

The IR absorption analysis was carried out using a Bruker 113v Fourier transform IR spectrometer. The

Fig. 1. Models for C_iO_i . (a) divalent oxygen model. (b) trivalent oxygen model. Gray, black and white atoms are Si, C and O. Crystallographic axes and principal directions of the B-tensor are also shown.

measurements were performed at 10 K and at room temperature (RT), with a spectral resolution of 0.5–1.0 cm^{-1} . Three types of Si:O,C samples were used. Sample (1) contained ^{16}O and ^{12}C , while sample (2) contained mainly ^{18}O and ^{12}C . Sample (3) was doped with ^{16}O and ^{13}C . Sample (1) was fabricated from ordinary phosphorus-doped Cz-Si with initial resistivity of 60 Ωcm , with oxygen and carbon concentrations of about 1×10^{18} and $3 \times 10^{17} \text{ cm}^{-3}$, respectively. Samples (2) and (3) consisted of float-zone Si material (Fz-Si) enriched with oxygen and carbon isotopes. In (2) the concentrations of $^{16}\text{O}_i$, $^{18}\text{O}_i$ and $^{12}\text{C}_s$ were 5×10^{16} , 1.5×10^{18} and $4 \times 10^{17} \text{ cm}^{-3}$, respectively, while (3) contained about $1 \times 10^{18} \text{ cm}^{-3}$ of $^{16}\text{O}_i$ and $1.5 \times 10^{18} \text{ cm}^{-3}$ of $^{13}\text{C}_s$. Irradiation with electrons (2.5 MeV) was performed at RT. Isochronal anneals of 30 min were carried out up to 600°C in nitrogen ambient.

Fig. 2 shows fragments of differential absorption spectra of electron-irradiated Si samples doped with different O and C isotope combinations. Table 1 gives band frequencies for neutral C_iO_i and their ^{13}C and ^{18}O isotopic shifts. In descending frequency, they are labeled as the 1116, 865, 742, 585, 550, 540 and 529 cm^{-1} bands, respectively. Other than the 585 and 540 cm^{-1} modes, the bands are the same as those given earlier [1,4]. However, only carbon isotope effects had previously been studied by IR-absorption, and shifts were only found for the 1116 and 865 cm^{-1} lines.

The most important result is the observation of a significant 33.4 cm^{-1} oxygen isotopic shift *only* for the 742 cm^{-1} band, clearly indicating its oxygen character. This shift is in agreement with observations based on PL vibrational spectroscopy [1]. The present work then clearly shows that the highest oxygen related frequency

Fig. 2. Sections of the absorption spectra measured at 10 K for electron-irradiated Si samples: (1) $[^{16}\text{O}] = 1 \times 10^{18}$ and $[^{12}\text{C}] = 3 \times 10^{17} \text{ cm}^{-3}$, irradiation dose $F = 1 \times 10^{18} \text{ cm}^{-2}$; (2) $[^{18}\text{O}] = 1.5 \times 10^{18}$, $[^{16}\text{O}] = 5 \times 10^{16}$ and $[^{12}\text{C}] = 4 \times 10^{17} \text{ cm}^{-3}$, $F = 1.5 \times 10^{18} \text{ cm}^{-2}$; (3) $[^{16}\text{O}] = 1 \times 10^{18}$, $[^{13}\text{C}] = 1.5 \times 10^{18}$ and $[^{12}\text{C}] = 2^{17} \text{ cm}^{-3}$, $F = 1.5 \times 10^{18} \text{ cm}^{-2}$. The lines related to the C_iO_i complex are labeled.

529.6	544.2	0.1	0.0	5.2	5.4

lies at 742 cm^{-1} , compared with 1136 cm^{-1} for O_i , and possesses an ^{18}O shift considerably smaller than that of the asymmetric stretch mode in O_i (51.4 cm^{-1}) [12].

The low intensity and spectral location have probably prevented the detection of the 585 cm^{-1} band previously. In Si: $^{16}\text{O}, ^{12}\text{C}$, the 585 cm^{-1} band is masked by the X-line at 588.5 cm^{-1} due to the C_sO_i pair, as well as the fundamental mode at 589.1 cm^{-1} of $^{13}\text{C}_s$ which occurs with a natural abundance of 1.1%. However, its slight shift in ^{18}O -doped material is enough to distinguish it, allowing us to correlate this with other bands of the C_iO_i defect.

There are some hints that another weak band at $\sim 540\text{ cm}^{-1}$ is associated with the C_iO_i complex and labeled 540? in Fig. 2. In Si: $^{16}\text{O}, ^{12}\text{C}$ this band is superimposed on bands at 540.4 and 543.3 cm^{-1} due to C_iC_s [13]. However, it undergoes a $\sim 1.5\text{ cm}^{-1}$ shift in Si: $^{18}\text{O}, ^{12}\text{C}$ samples suggesting an oxygen defect. Moreover, since its isochronal annealing behavior is essentially the same as that of the other C_iO_i -related lines, we tentatively identify it with this defect.

3. Theory and modeling

We used an ab initio total energy density functional code (AIMPRO), with 64 Si-atom supercells. Details are described elsewhere [14]. LVMs were calculated by diagonalization of the dynamical matrix obtained from the ab initio code. Acceptor and donor levels are obtained by comparing energy differences $E(-) - E(0)$ and $E(0) - E(+)$ of a defect, with those of a standard defect with well-known acceptor and donor levels [15]. This was chosen to be the carbon-interstitial defect with acceptor and donor levels at $E_c - 0.10\text{ eV}$ and $E_v + 0.28\text{ eV}$, respectively. The stress-energy tensor B was calculated by deforming the defective supercell with a set of strain-tensors compatible with the symmetry of the defect, and solving $\Delta E = B \cdot \varepsilon$ [13].

In agreement with previous calculations [6], we find a ground state structure of C_iO_i , with both carbon and oxygen three-fold coordinated, forming two vertices of a ring as shown in Fig. 1b. Its 1.7 eV binding energy is consistent with its high thermal stability. Calculation of the energy levels shows that a deep donor level lies at $E_v + 0.36\text{ eV}$ in agreement with the observed DLTS level at $E_v + 0.38\text{ eV}$ [5]. No acceptor or second donor levels were found. A Mulliken bond population analysis of the highest occupied band gives 25.4% and 0.1% of spin density localized around the carbon and oxygen atoms respectively. The first is in agreement with the 28.6% spin localization on carbon measured for G15 [2]. Note that in spite the O-atom being over-coordinated, no gap level with overlap on oxygen occurs. Both the lone electron pair on O, and the donated electron pair in the $\text{Si}_2\text{-O}$ bonding state, resonate the valence band.

The principal directions of the calculated stress-energy tensor are shown in Fig. 1b. The C_{1h} symmetry of the defect implies that one principal direction (corresponding to the B_2 component) lies along $[1\ 0\ \bar{1}]$, but the other directions are rotated by an angle θ_B from the $[0\ 1\ 0]$ and $[1\ 0\ 1]$ axes. For the positively charged defect, the rotation angle is calculated to be $\theta_B = 22^\circ$, and the principal values of the tensor are 8.5, 2.3 and -11.8 eV for B_1 , B_2 and B_3 , respectively. Stress alignment experiments give 8.6, 0.2 and -8.8 eV for B_1 , B_2 and B_3 , and $\theta_B = 15^\circ$. Hence the model accounts well the observations.

The LVMs for the neutral defect are shown in Table 1. Of special interest is the unique oxygen-related mode lying at 760 cm^{-1} — well below the asymmetric stretch mode for interstitial oxygen at 1136 cm^{-1} . This is a characteristic of the weakened bonds of over-coordinated oxygen relative to those in Si-O-Si . The oxygen mode is very close to the observed band at 742.8 cm^{-1} . The observed and calculated ^{18}O -shifts are also very close, lying at 33.4 and 35.6 cm^{-1} respectively. Two carbon related modes are calculated to lie at 1138 and 876 cm^{-1} , close to the observed 1116 and 865 cm^{-1} bands. Their shifts with ^{13}C demonstrate that they are carbon related in agreement with the observations.

The four remaining low frequency modes at 593, 556, 545 and 544 cm^{-1} have not been assigned previously. They arise from vibrations of Si neighbors to the defect core, and are properly described only when energy second derivatives with these atoms are calculated directly from the ab initio program. These support the assignment of the 540 cm^{-1} band to C_iO_i (see Section 2).

4. Conclusions

Absorption bands produced by the C_iO_i defect have been studied in detail. FTIR data were obtained from Si samples doped with three combinations of dominant

oxygen and carbon isotopes, including for the first time the effect of ^{18}O . According to the calculations, we classify the LVMs as carbon-related 1116 and 865 cm^{-1} bands, the oxygen 742 cm^{-1} band, and the four low frequency 585 , 550 , 540 , 529 cm^{-1} bands, where the 585 and 540 cm^{-1} bands have not been reported previously. Of particular interest is the position and ^{18}O isotopic shift observed for the 742 cm^{-1} band (33.4 cm^{-1}), much less pronounced than that of O_i (51.4 cm^{-1}) [12]. These appear to be characteristic of oxygen over-coordination. The stress-energy tensor agrees well with the measurements, further supporting the ring structure found for the defect.

Expanded model for anharmonic vibrational excitation of oxygen in silicon

H. Yamada-Kaneta*

Nano-electronic Materials Laboratories, Fujitsu Laboratories Limited, 10-1 Morinosato-Wakamiya, Atsugi 243-0197, Japan

Abstract

To consistently describe the infrared absorptions by the oxygen in silicon discovered previously (30-, 1100-, 1200-, and 1700-cm⁻¹ bands) and recently (600- and 1800-cm⁻¹ bands), our original model for the two-dimensional low-energy excitation of oxygen coupled to the A_{2u} local mode has been expanded so as to include the coupling to the A_{1g} local mode. In addition to the four unknown parameters contained in our original model, the expanded model contains two more parameters: the A_{1g} mode frequency and the A_{1g}-mode coupling constant. Employing the set of appropriate basis functions of sufficient size, we calculated the Hamiltonian matrix and then diagonalized it numerically. We have found the parameter values that well reproduce the energy levels we previously determined up to one-A_{2u}-phonon plus one-A_{1g}-phonon states. © 2001 Elsevier Science B.V. 1. Introduction

In spite of the simple structure, the bond-interstitial oxygen in silicon (Si–O–Si center) causes the many infrared absorption lines that are classified into the 30-, 600-, 1100-, 1200-, 1700-, and 1800-cm⁻¹ bands, as summarized in Table 1 of Ref. [1]. Our earlier model for the impurity excitation of the Si–O–Si center took into account the two-dimensional (2D) low-energy anharmonic excitation (LEAE) of the oxygen and its coupling to the A_{2u} local mode [2]. Hereafter, we refer to this excitation as the *A_{2u}-mode-coupled 2D LEAE*. Our calculation described the energy levels (Fig. 4(a) in Ref. [2] and Fig. 2 in Ref. [3]¹) that well explain the

energies of the lines in the 30-, 1100-, and 1200-cm⁻¹ bands. We pointed out that the 1700-cm⁻¹ band could be a replica of the 1100-cm⁻¹ band caused by the interaction between the A_{2u}-mode-coupled 2D LEAE and the hypothetical A_{1g} local mode of an energy of about 613 cm⁻¹ [2]. Since then, existence of the A_{1g} local mode has been supported by many theoretical [4,5] and experimental [6,7] investigations.

Recent discoveries of the main lines in the 600- [6] and 1800-cm⁻¹ bands [7], together with our discovery and detailed investigation of the line-structure around them [1], were very important for us to uncover the overall energy-level scheme of the local-mode-coupled 2D LEAE: Combining the experimental findings for these new lines [1,6,7] with the previously determined energy-level scheme [2,3] of the A_{2u}-mode-coupled 2D LEAE, we determined the relevant part of the total energy levels (eigenenergies) up to nearly 1900 cm⁻¹. This is shown in Fig. 1. Hereafter we refer to these total energy levels (eigenenergies) as the *experimentally* determined ones. We suggested [1] that these total energy levels and thus, the observed infrared absorptions could be described by considering that the 2D LEAE is coupled not only to the

¹ It should be noted that there is a careless mistake in Fig. 2 of Ref. [3]. In the figure, the assignment of the 43.3-cm⁻¹ line and 49-cm⁻¹ line should be inverted: the former and the latter lines are assigned to the transitions $|0, \pm 2\rangle \rightarrow |0, \pm 3\rangle$ and $|0, \pm 1\rangle \rightarrow |1, 0\rangle$, respectively.

Fig. 1. Calculated eigenenergies of the two-dimensional low-energy anharmonic excitation of the oxygen coupled to the A_{2u} and A_{1g} local modes. These calculated (Cald.) eigenenergies given on the rightmost side are compared with the previously obtained [1] experimental (Exptl.) values of the eigenenergies which are given by each energy level. Here, the "experimental values of the eigenenergies" mean the eigenenergies determined by incorporating the values of the measured line-energies with the result of line assignment obtained theoretically and/or experimentally [1,2]. The previously obtained result for the line assignment is also shown. The lines observed in each absorption band are assigned to the transitions represented by the arrows. The values given by the arrows are the measured energies of the lines assigned to the indicated transitions. The calculated eigenenergies shown here are those obtained for the adjusted parameter values of the Set 1 given in Table 1.

A_{2u} local mode but also to the A_{1g} local modes. In other words, we determined the total energy levels up to the one- A_{2u} -phonon plus one- A_{1g} -phonon states ($M = N = 1$ states) [1]. Derivation of these total energy levels (Fig. 1) was based on our consideration that the 600-cm⁻¹ band is due to the transition dipole operators of the (x,y)-symmetry; namely, the (x,y)-displacement of the oxygen. Our recent experiment of the stress-induced dichroism of the main line at 648.2 cm⁻¹ has uncovered that this line is actually due to the transition dipoles of the (x,y)-symmetry [8], confirming our total energy-level scheme.

However, these total energy levels we obtained are not the result of theoretical treatment, but they are experimentally derived one's, in some sense. The purpose of this work is to demonstrate that the total energy levels we determined up to one- A_{2u} -phonon plus one- A_{1g} -phonon states (Fig. 1) can be described actually by adding the A_{1g} -mode coupling term to our original model Hamiltonian.

2. Hamiltonian and method of calculation

In the mathematical explanation below, we adopt the same notations and follow the same coordinate axes as introduced in our original paper [2]. Our original Hamiltonian for the A_{2u} -mode-coupled 2D LEAE is expressed by Eq. (5) in Ref. [2]:

$$\mathcal{H} = H^{(0)} + H^{(A_{2u})} + W^{(A_{2u})}, \quad (1)$$

where the three terms on the right-hand side represent, respectively, the 2D LEAE of the oxygen around the z -axis, the A_{2u} local mode, and the coupling between them. Due to the z -axial symmetry of the potential for the 2D LEAE, the angular momentum ℓ is a good quantum number. Approximating $W^{(A_{2u})}$ by $W^{(A_{2u})}$ described by Eq. (7) in Ref. [2], we obtain another good quantum number N : the phonon number of the A_{2u} local mode. Accordingly, the eigenstates are represented as $|k, \ell, N\rangle$, where k distinguishes the eigenstates having the same (ℓ, N) .

We next introduce the interaction between the A_{2u} -mode-coupled 2D LEAE and the A_{1g} local mode. We first examine qualitatively the following two candidates for the interaction terms that may describe the absorption lines in the 600-, 1700-, and the 1800-cm⁻¹ bands:

$$W^{(A_{1g})} = g_{A_{1g}} r^2 Q_{A_{1g}}, \quad (2)$$

$$\tilde{W}^{(A_{1g})} = \tilde{g}_{A_{1g}} Q_{A_{2u}}^2 Q_{A_{1g}}. \quad (3)$$

We proposed [2] that the interaction term (3) actually reproduces one- A_{1g} -phonon replica of the energy levels of one- A_{2u} -phonon states which are lying in the range 1136–1246 cm⁻¹. We speculated that this is how the 1700-cm⁻¹ band appears. However, we recently found that, if we apply the first order perturbation theory to the interaction (3), the oscillator strengths calculated by using the perturbed eigenfunctions vanish for the lines in the 600-cm⁻¹ band, contradicting the experiment. Thus, here we introduce the interaction term (2). As the first step of expanding our earlier model, we employ here the interaction term (2) only. We thus start with the following total Hamiltonian H :

$$H = H^{(0)} + H^{(A_{2u})} + W^{(A_{2u})} + H^{(A_{1g})} + W^{(A_{1g})}, \quad (4)$$

where $H^{(A_{1g})} \equiv \hbar \omega_{A_{1g}} b_{A_{1g}}^\dagger b_{A_{1g}}$ represents the A_{1g} local mode. The total Hamiltonian H is still axially

symmetric, and commutative with the A_{2u} phonon number operator $b_{A_{2u}}^\dagger b_{A_{2u}}$. Thus the eigenstates of H can still be specified by the good quantum numbers ℓ and N . However, the phonon number $M (= 0, 1, 2, \dots)$ of the A_{1g} local mode is no longer a good quantum number of H , because of the presence of the interaction term $W^{A_{1g}}$ that is not commutative with the A_{1g} phonon number operator. So far, we often adopted the A_{1g} phonon number M to specify the eigenstates of the total coupled system [1], namely, $|k, \ell, N, M\rangle$. Here we see that we can just regard M as an *approximate* good quantum number, only when the A_{1g} -mode interaction is weak enough. The present Hamiltonian (4) contains six unknown parameters: the coefficients α and β of the quartic potential for the 2D LEAE, the A_{2u} mode frequency $\omega_{A_{1g}}$, the A_{2u} mode coupling constant $g_{A_{2u}}$, the A_{1g} mode frequency $\omega_{A_{1g}}$, and the A_{1g} mode coupling constant $g_{A_{1g}}$.

We represent the total Hamiltonian in the matrix form by using the following basis functions:

$$|k, \ell, N, M\rangle \equiv [1/(2\pi)^{1/2}] e^{i\ell\varphi} \zeta_{k|\ell}(r, \varphi) |N\rangle |M\rangle, \quad (5)$$

where the part of the arguments (r, φ) on the right-hand side is the eigenfunction of a 2D harmonic oscillator of an appropriate excitation energy. The $|N\rangle$ and $|M\rangle$ are the N th and M th eigenfunctions of the A_{2u} and A_{1g} local modes, respectively. The analytical expressions for the matrix elements

$$\langle (k, \ell, N, M | H | k', \ell', N', M') \rangle \quad (6)$$

can be easily derived by the similar method as in the original paper [2]. Since the matrix of H is sub-diagonal with respect to ℓ and N , we only have to diagonalize each submatrix specified by (ℓ, N) . We employed 40–50 basis functions for the harmonic oscillator part (i.e., the maximum number of k of the employed basis functions is 40–50), and 8–12 basis functions for the part of the A_{1g} local mode. Thus the size of the submatrix for each (ℓ, N) was nearly 320–600 dimensional. We numerically diagonalized these submatrices, and ascertained that the obtained relevant eigenvalues converged to their 6–7th significant figures.

3. Result of calculation

We adjusted the parameters $(\alpha, \beta, \omega_{A_{2u}}, g_{A_{2u}}, \omega_{A_{1g}}, g_{A_{1g}})$ so that the calculated eigenenergies would well fit with those obtained experimentally [1] which are given by each energy level in Fig. 1. The eigenenergies calculated for the adjusted parameter values of Set 1 (Table 1) are given on the rightmost side of Fig. 1. We see that the calculation has well reproduced the experimentally determined eigenenergies written by each energy level. As a quantity to indicate how the calculated eigenenergies are close to the experimentally

Table 1

Similar values of mean square deviation σ evaluated for different sets of the adjusted parameter values

Model parameters and mean square deviation σ	Set 1	Set 2	Set 3	Set 4
α (meV/Å ²)	−13.129	−13.563	−13.249	−13.118
β (meV/Å ⁴)	236.84	264.72	243.96	236.02
$\hbar\omega_{A_{2u}}$ (meV)	142.87	142.89	142.85	142.87
$\hbar g_{A_{2u}}/\omega_{A_{2u}}$ (meV/Å ²)	−26.770	−26.957	−26.626	−26.798
$\hbar\omega_{A_{1g}}$ (meV)	76.427	76.382	76.414	76.428
$g_{A_{1g}}(\hbar/2\omega_{A_{1g}})^{1/2}$ (meV/Å ²)	−12.028	−46.522	−26.325	−9.161
σ (cm ^{−1})	1.61	1.62	1.61	1.61

determined ones, we introduce the following mean square deviation σ :

$$\sigma \equiv \left[(1/n) \sum_{i=1}^n (E_i^{(\text{calc})} - E_i^{(\text{exptl})})^2 \right]^{1/2}, \quad (7)$$

where $E_i^{(\text{calc})}$ and $E_i^{(\text{exptl})}$ are the i th calculated and the experimentally determined eigenenergies, respectively. In Table 1, we also presented the values of σ . For the parameter values of the Set 1, we obtained $\sigma = 1.61 \text{ cm}^{-1}$, which means that the calculated eigenenergy deviates by 1.61 cm^{-1} on average, from the corresponding experimental value. In spite of our use of only the simplest (lowest order) interaction term (2) only, agreement between the calculated and the experimentally determined eigenenergies is fairly good. We have actually seen that the expanded model Hamiltonian (4) well reproduces the eigenenergies previously determined up to one- A_{2u} -phonon plus one- A_{1g} -phonon states, i.e., the states of $M = N = 1$.

4. Discussion

As seen from Table 1, for the other sets of the parameter values, Sets 2–4, the calculation reproduces the previously determined (experimentally determined) total energy levels, with similar small value of $\sigma (= 1.61 \text{ cm}^{-1})$. We see that, the obtained (adjusted) values of the parameters α , $\omega_{A_{2u}}$, $g_{A_{2u}}$, and $\omega_{A_{1g}}$ are nearly the same for all sets. The value of β and $g_{A_{1g}}$ vary, with the value of σ kept unchanged. We further see that for the larger $g_{A_{1g}}$, we have the larger value of β . This suggests, that the strong A_{1g} -mode coupling reduces the effect of β . In other words, in the case of strong A_{1g} -mode coupling, the effective values of β is reduced from the obtained one shown in Table 1. This can be actually shown by the method of adiabatic approximation for the A_{1g} -mode coupling (2). The coupling is renormalized into the coefficient β of the fourth order term of the 2D

LEAE potential, to give an effective β that is smaller than the original one.

As pointed out above, the different parameter values equally well reproduce the experimentally determined total energy levels. The best way of obtaining (fixing) the true parameter values would be to examine whether or not the calculated intensity ratio of the main lines belonging to the different bands agrees with the corresponding experimental value: for example, the ratio of the intensity of the 648.2-cm^{-1} line to that of the 29.25-cm^{-1} line. The parameter values that reproduce the total energy levels and the line-intensity ratio at the same time would be the reliable ones. This kind of test calculation for the true parameter values is the next problem to be dealt with.

In conclusion, we have demonstrated theoretically that, by adding the A_{1g} -mode coupling to our original model Hamiltonian, we can reproduce the energy levels up to one- A_{2u} -phonon plus one- A_{1g} -phonon states. In order to uniquely determine the parameter values, we

have to examine the line-intensity ratio calculated for the parameter values that well describe the total energy levels.

Abstract

It is known that the application of high hydrostatic pressure on Si during heat treatment produces substantial changes in the properties of oxygen precipitates, which in turn, affect the behavior of various defects present in the crystal lattice. In this work, the annealing behavior of the VO complexes in Si samples subjected, before neutron irradiation, to different High Temperature–High Pressure (HT–HP) treatments at temperatures around 900°C and pressures up to 12 kbar, for $t = 5$ h, was investigated using Infrared spectroscopy. We found that (i) the samples pre-treated at $T_1 = 870^\circ\text{C}$ and $T_2 = 957^\circ\text{C}$, at atmospheric pressure and (ii) the samples pre-treated at $P_1 = 1$ bar and $P_2 = 12$ kbar, at $T_1 = 870^\circ\text{C}$, exhibit approximately the same difference in the annealing temperature of the VO complexes. The observed effect is explained by taking into account the impact of the HT–HP pre-treatment on the fraction of the self-interstitials bound at the SiO_x/Si interface of the oxygen precipitates and the Si matrix. We argue that the two regimes of pre-treatments (i) and (ii), see above, produce the similar effects upon self-interstitial aggregation processes in the presence of oxygen precipitates. © 2001 Elsevier Science B.V. Keywords: Silicon; Irradiation; High-pressure anneals

1. Introduction

High temperature (HT) treatment at $T > 400^\circ\text{C}$ of silicon crystals leads to the appearance [1] of structural defects such as various kinds of oxygen aggregates and precipitates, rod-like defects, dislocations, stacking faults and so on. These defects, in general, affect the properties and the behavior of the radiation-induced defects. It has been found [2], for instance, that the annealing temperature of the VO defects is considerably changed by variations in the duration of pre-heat treatment at $T = 600^\circ\text{C}$ and/or the initial oxygen concentration of the Czochralski silicon (Cz-Si). It was

suggested [2] that the annealing of the VO defects takes place through the capture of Si self-interstitials (Si_i 's) released from the SiO_x/Si interface of the Si matrix and the oxygen precipitates being formed after the 600°C pre-heat treatment. The Si_i 's generated [3,4] during the precipitation process tend to aggregate [5]. They generally form extended structural defects such as stacking faults. Reasonably, it is expected that the annealing process of the A-centers would be affected by the state and the ability of these Si_i 's to be released from the aggregates.

In order to understand the phenomenon, it is necessary to consider the effects on the Si_i 's due to the different kinds of oxygen aggregates and structural defects formed during pre-HT treatments at different temperatures. As a result of the HT treatment and the consequent formation of precipitates and structural

*Corresponding author. Tel.: +30-1-727-4726; fax: +30-1-725-7689.

E-mail address: hlontos@cc.uoa.gr (C.A. Londos).

defects, stress fields are locally created [6] around the precipitates and the extended defects. These elastic fields are anisotropic in general and attract the emitted Si_i 's. Concerning now, the annealing of the VO defects, the relation of the self-interstitial aggregates with the precipitates and the structural defects play a very important role, according to our opinion. The grade of binding of the self-interstitial aggregates is very significant, since it is expected to be different for different dominating precipitates and, therefore, for different temperatures of the HT treatments. Evidently, the Si_i 's, loosely bound at the interface are responsible for the dependence of the annealing behavior of the A-centers on the temperature of the pre-heat treatment. We assume that the binding force on the Si_i 's changes with increasing temperature, due to changes in the oxygen precipitates, i.e. their density, their shape and/or their size upon pre-heating. More specifically, we assume that pre-heating at two temperatures T_1 and T_2 with $T_2 > T_1$, results in a situation that the Si_i 's are more tightly bound at the interface in the latter temperature, T_2 . In other words, the Si_i 's are more effectively released during the course of the isochronal anneal in a material subjected to the lower temperature T_1 of pre-heat treatment.

On the other hand, the application of enhanced hydrostatic pressure during heat treatment has been found [7] to affect a lot of the features of the structural defects and the oxygen aggregates as, for example, the concentration of the dislocations, the density and the size of the precipitates and concentrations of the remaining oxygen interstitials, etc. Thus, pressure is another important parameter, which is expected to affect the behavior of the radiation defects, since every HT-HP pre-treatment establishes a different relation between the self-interstitial aggregates and the precipitates.

The purpose of this work was to investigate the annealing behavior of the VO defects and monitor the changes in the annealing temperature in dependence on the conditions of a HT-HP pre-treatment. We shall show that by considering that the binding of the Si_i 's at the SiO_x/Si interface depends on the HT-HP pre-treatment, we can explain the obtained experimental results of this study.

2. Experimental details

Five Cz-grown silicon samples with nearly the same initial oxygen concentrations ($O_i = 8.3 \times 10^{17} \text{ cm}^{-3}$), were subjected to different combinations of HT-HP pre-treatments, for the same time, $t = 5 \text{ h}$; see Table 1. Then, the samples were irradiated by fast neutrons at $T \approx 50^\circ\text{C}$. The fluence was about 10^{17} n/cm^2 . Afterwards, 15 min isochronal anneals were performed in steps of $\sim 10^\circ\text{C}$. After each annealing step, we employed IR measurements to monitor the annealing behavior of the 828 cm^{-1} LVM band of the VO defect.

3. Experimental results and discussion

In Table 1, the annealing temperature (T_{ann}) of the VO defects is indicated, for each sample. As seen, the beginning of the annealing process, i.e. T_{ann} , was found to be different for the different pre-HT-HP treatment regimes. It is well known that among a number [8] of available reaction paths, two reactions are the most important when the A-centers become mobile: $\text{VO} + \text{O}_i \rightarrow \text{VO}_2$, $\text{VO} + \text{Si}_i \rightarrow \text{O}_i$. These two reactions run in parallel, at least in the temperature range where the VO centers disappear and the VO_2 defects are formed. The emergence of the VO_2 defect in the IR spectra is related to the first reaction. An increase in the $[\text{O}_i]$ concentration observed during the VO decay verifies [9] that the second reaction takes place as well.

Let us now compare the behavior of the samples S_1 and S_2 , which were annealed at temperatures of $T_1 = 870^\circ\text{C}$ and $T_2 = 957^\circ\text{C}$, at atmospheric pressure. In these cases, the annealing temperatures of the VO defects are $T_{1\text{ann}} = 270^\circ\text{C}$ and $T_{2\text{ann}} = 292^\circ\text{C}$, respectively ($T_{2\text{ann}} > T_{1\text{ann}}$). First of all, we see that the annealing temperature is lower in both cases than the normal annealing temperature of the VO defects (about 300°C) [10] in silicon samples without any pre-heat treatment, a phenomenon being well known and discussed in the literature [2,6]. If the first reaction $\text{VO} + \text{O}_i \rightarrow \text{VO}_2$ is dominating in the annealing process,

Table 1
The annealing temperature T_{ann} of the VO defect for the various pre-HT-HP treated samples

Samples	T ($^\circ\text{C}$)	P (kbar)	t (h)	T_{ann} of the VO ($^\circ\text{C}$)	Comparison of T_{ann} ($^\circ\text{C}$)
S_1	870	10^{-3}	5	270 ± 4	$\Delta T_{12\text{ann}} = +22$
S_2	957	10^{-3}	5	292 ± 2	$\Delta T_{13\text{ann}} = +15$
S_3	870	12	5	285 ± 3	$\Delta T_{24\text{ann}} = +2$
S_4	957	12	5	290 ± 3	$\Delta T_{34\text{ann}} = +5$
S_5	900	12	5	284 ± 4	$\Delta T_{15\text{ann}} = +14$

then, one could expect that a larger increase in the oxygen diffusivity (and that of A-centers as well) in the case of pre-heat treatment at the higher temperature, would lead to a faster reaction between VO and O_i , resulting in a lower annealing temperature of the A-centers in the sample S_2 than in the sample S_1 . This expectation is opposite to what is observed (see Table 1). Therefore, the first reaction cannot provide a plausible explanation of the experimental data. Other factors should be taken into account, as well. If however, the second reaction $VO + Si_i \rightarrow O_i$ is the prevailing one, then one should consider the sources of the Si_i 's. These sources are oxygen aggregates and precipitates, which as we mentioned in the introduction, produce different strains in the lattice due to differences in their forms, as a result of the different pre-heat treatments.

Let us consider the sample S_1 subjected to a heat treatment at the lower temperature, $T_1 = 870^\circ\text{C}$. Si_i 's, if loosely bound to oxygen aggregates can be emitted and interacted with A-centers, (no matter whether A-centers are coming towards the precipitates or Si_i 's are emitted from the precipitates), as the temperature increases during the isochronal annealing sequence. This leads to a lower conversion temperature of the VO into the VO_2 , $T_{1\text{ ann}} = 270^\circ\text{C}$. However, in the case of the sample S_2 subjected to a higher temperature of heat treatment, $T_2 = 957^\circ\text{C}$, the dominating oxygen precipitates are different and, therefore, the binding of the Si_i 's is also different, compared to the sample S_1 . We assume that the Si_i 's are more tightly bound in this case. This means that it is more difficult to be emitted from the precipitates or in other words, the reaction $VO + Si_i \rightarrow O_i$, is now more difficult to realise. Alternatively, a higher temperature should be achieved in sample S_2 in order that the reaction $VO + Si_i \rightarrow O_i$ becomes significant. Notice now that this reaction results in the decay of A-centers, i.e. the concentration of A-centers is lowered and from reaction kinetics arguments, it is expected that the lower the concentration of A-centers, the higher the temperature of their conversion into the VO_2 complexes. Indeed, this was found experimentally ($T_{2\text{ ann}} = 292^\circ\text{C}$).

We shall now extend our model involving also the application of uniform stress during the pre-heat treatment process. Within the line of our argumentation, we suggest that an increase of stress (from 1 bar to 12 kbars) at a certain low temperature (870°C here) produces equivalent effect on the annealing temperature of the VO defects with an increase of the temperature (from 870°C to 957°C) at certain low stress (1 bar here). In other words, the increase of stress at low temperature ($T = 870^\circ\text{C}$) contributes to a change in the kind of the dominating precipitates (and the consequent binding of the Si_i 's at the interface), which is equivalent to the increase of temperature at low stress ($P = 1$ bar). Thus, comparing the samples S_1 and S_3 (see Table 1), we

actually see an increase of T_{ann} ($\Delta T_{13\text{ ann}} = 15^\circ\text{C}$) which is comparable to the increase of T_{ann} in the case of the samples S_1 and S_2 ($\Delta T_{12\text{ ann}} = 22^\circ\text{C}$).

Two additional observations should be reported:

(i) Annealing of the samples at high T (957°C here) should have practically no effect in the annealing temperature T_{ann} , irrespectively, of a low ($P = 1$ bar) or a high ($P = 12$ kbars) pressure applied during the anneal, since at high T (957°C), the precipitates have attained their final form and the application of pressure has no further effect on the binding of the Si_i 's at the interface. Actually, this is the case concerning the samples S_2 and S_4 , for which the annealing temperatures of the VO defects are practically the same; cf. $T_{2\text{ ann}} = 292^\circ\text{C}$ and $T_{4\text{ ann}} = 290^\circ\text{C}$ (Table 1).

(ii) On the other hand, if high stress (12 kbars here) is applied, the annealing temperature should not depend on the temperature of the pre-treatment (a low one $T_1 = 870^\circ\text{C}$ and a high one $T_2 = 957^\circ\text{C}$ here) since the oxygen precipitates have attained the final form due to the increase of pressure and that which is not affected by the increase of the temperature of the heat treatment. Actually, this is the case concerning the samples S_3 and S_4 which exhibit approximately equal annealing temperatures, i.e. $T_{3\text{ ann}} = 285^\circ\text{C}$, $T_{4\text{ ann}} = 290^\circ\text{C}$.

(iii) It is worth also noting that the sample S_5 , which has been subjected to a HT-HP treatment at $P = 12$ kbars but at an intermediate temperature $T_3 = 900^\circ\text{C}$ ($T_1 < T_3 < T_2$), shows an intermediate increase of $\Delta T_{\text{ann}} \approx 14^\circ\text{C}$, as one would expect from our model.

4. Conclusions

We have studied the annealing behavior of Cz-grown Si samples subjected to different HT-HP treatments prior to neutron irradiation. We have found that these treatments affect the annealing temperature of the VO center. More specifically, it has been found that (i) pre-treatments on two samples at temperatures $T_1 = 870^\circ\text{C}$ and $T_2 = 957^\circ\text{C}$, respectively, at $P = 1$ bar, cause the same change in the annealing temperature of the VO defects as (ii) pre-treatments on two samples at pressures $P_1 = 1$ bar and $P_2 = 12$ kbars, respectively, at the low temperature $T_1 = 870^\circ\text{C}$. We have explained the results by considering the effects of the HT-HP treatment on the grade of binding of the Si_i 's at the SiO_x/Si interface.

Abstract

Pronounced oxygen segregation in helium-implanted Czochralski silicon, Cz-Si:He, treated at 1000–1400 K under atmospheric or enhanced, up to 1.2×10^9 Pa, hydrostatic pressure, HP, is observed. Annealing of hydrogen-implanted Cz-Si:H at 720–920 K– 10^5 Pa also results in the oxygen accumulation in the damaged volume while no accumulation is detected at ≥ 1 GPa and at ≥ 1230 K. The HP effect on transformation of post-implantation defects and on oxygen diffusivity can be responsible for oxygen accumulation in Cz-Si:(He, H). © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si:He; Si:H; Hydrostatic pressure; Oxygen accumulation

1. Introduction

Defect formation in silicon implanted with helium (inert dopant) or hydrogen (creating a weak H–Si bond) has become, in last years, a topic of considerable interest, both for practical reasons (gettering of contaminants and “smart cut” process) and for the extraordinary gas pressures attained in He/H-filled clusters and bubbles created upon annealing [1,2].

Enhanced hydrostatic pressure (HP) of inert gas (Ar) at annealing (HT-HP treatment) of He- and H-implanted silicon affects strongly its structure [3,4]. The effect of stress induced by enhanced Ar pressure on accumulation (gettering) of oxygen in He- and H-

implanted Czochralski silicon (Cz-Si) is the main subject of the present work.

2. Experimental

Cz-Si wafers (of 001 orientation), with concentration of interstitial oxygen, c_o , up to $1 \times 10^{18} \text{ cm}^{-3}$, were implanted with helium (Cz-Si:He, He^+ doses, $D = 5 \times 10^{15} - 3 \times 10^{17} \text{ cm}^{-2}$, energy $\leq 300 \text{ keV}$, He^+ projected range, $R_p \leq 1.35 \mu\text{m}$) or hydrogen (Cz-Si:H, H_2^+ dose $4 \times 10^{16} \text{ cm}^{-2}$, energy 130 keV, $R_p = 0.5 \mu\text{m}$).

Cz-Si:He and Cz-Si:H were treated under Ar pressure up to 1.2 GPa at temperature up to 1400 K for up to 10 h. The defect structure of the samples was investigated by transmission electron microscopy (TEM), X-ray reciprocal space mapping (XRRSM) and synchrotron topography done at HASYLAB, Hamburg. Oxygen and hydrogen depth profiles in the

annealed/treated samples were determined by secondary ion mass spectrometry (SIMS).

3. Results and discussion

The He implantation into Si results in creation of disturbed He-containing zone near R_p . The kind and concentration of defects (mostly He-filled clusters and bubbles) are dependent on He dose and energy, substrate temperature (in our case ≤ 350 K) as well as on the conditions of subsequent annealing/HT-HP treatment. During the annealing He atoms escape the Si matrix; this He removal is increasing with temperature [4].

TEM image of Cz-Si:He sample treated at 870 K is presented in Fig. 1. Annealing of such samples at 1270 K- 10^5 Pa for 1 h results in creation of bubbles while only dislocations were detected in Cz-Si:He ($c_0 = 1 \times 10^{18} \text{ cm}^{-3}$, $D = 5 \times 10^{16} \text{ cm}^{-2}$, 150 keV, $R_p = 0.88 \mu\text{m}$) treated at 1270 K-1.15 GPa for 1 h. As it follows from XRRSM, enhanced HP results in decreased intensity of X-ray diffuse scattering, an evidence of a better structural perfection of HT-HP treated Cz-Si:He as compared to that annealed at 10^5 Pa.

No oxygen accumulation at implantation-damaged zone was detected for Cz-Si:He ($D = 5 \times 10^{16} \text{ cm}^{-2}$)

Fig. 1. TEM image of Cz-Si:He sample ($c_0 = 1 \times 10^{18} \text{ cm}^{-3}$, $D = 5 \times 10^{16} \text{ cm}^{-2}$, 300 keV, $R_p = 1.35 \mu\text{m}$) treated at 870 K-1.1 GPa for 10 h.

annealed below 1000 K at 10^5 Pa. The treatment under 1.1–1.2 GPa at 870–1000 K for 10 h results in the SIMS-detectable oxygen accumulation at damaged areas. Both the annealing and HT-HP treatment at 1270–1400 K results in the accumulation (Fig. 2).

Hydrogen implantation into Si also leads to creation of disturbed H-containing region. The generated H-filled clusters/bubbles are dependent on H dose and energy, temperature ($T \leq 470$ K) as well as on conditions of the annealing. During the annealing/HT-HP treatment H atoms outdiffuse from the Si matrix, the H loss being substantially suppressed under HP [3].

TEM image of the Cz-Si:H sample treated at 920 K-1.2 GPa is presented in Fig. 3. Two different disturbed areas were detected. The first one at a depth of 0.45–0.55 μm , corresponding to R_p of the main implanted species, H_2^+ , contains small bubbles and dislocations; the second one at the 0.8–1.0 μm depth originated from single H^+ ions present in the implanting beam and exhibits comparatively large bubbles. The prolonged annealing/treatment at temperatures up to 1400 K resulted in complete removal of hydrogen; however, numerous dislocations were still detected in Cz-Si treated at 1320 K-1.2 GPa for $t = 0.5$ h.

As it can be deduced from XRRSM [3,4] and synchrotron topographs, the intensity of X-ray diffuse scattering is lower and overall structural perfection is better in the case of the HT-HP treated Cz-Si:H samples, as compared to that annealed at 10^5 Pa.

The as-implanted Cz-Si:H sample ($c_0 = 8 \times 10^{17} \text{ cm}^{-3}$) indicated no oxygen accumulation near R_p ; annealing of that sample at 720 K- 10^5 for 0.5 h resulted

Fig. 2. SIMS depth profiles of oxygen in Cz-Si:He samples ($c_0 = 1 \times 10^{18} \text{ cm}^{-3}$, $D = 5 \times 10^{16} \text{ cm}^{-2}$, 150 keV, $R_p = 0.88 \mu\text{m}$) annealed/treated at 1270 K for 1 h.

Fig. 3. TEM image of Cz-Si:H sample ($c_0 = 8 \times 10^{17} \text{ cm}^{-3}$, $D = 4 \times 10^{16} \text{ cm}^{-2}$, 130 keV, $R_p = 0.5 \mu\text{m}$) treated at 920 K-1.2 GPa for 0.5 h.

in a marked oxygen gettering by defects in the implantation-damaged layer (Fig. 4) and in hydrogen loss. The Cz-Si:H samples treated at (720–920) K-(1.1–1.2) GPa for up to 1 h do not indicate the oxygen accumulation (Fig. 5). Some traces of that accumulation were detected in Cz-Si:H treated at 920/1070 K-1.1 GPa for ≥ 1 h, while no accumulation was detected for the samples annealed at 1320 K- 10^5 Pa or treated at (1230–1370) K-(1–1.2) GPa.

The major differences, in respect of oxygen accumulation in Cz-Si:He vs. Cz-Si:H can be outlined as follows:

- Oxygen accumulation was detected only in Cz-Si:He annealed at $> 1000 \text{ K}-10^5 \text{ Pa}$; HP resulted in more pronounced gettering of oxygen. It is contrary to the case of Cz-Si:H where oxygen accumulation was detected upon annealing at 720–870 K- 10^5 Pa .
- High HP in Cz-Si:H treated at 720–870 K and at higher temperatures prohibited oxygen accumulation in damaged areas.

Effect of oxygen accumulation in implantation damaged and in the near-surface areas of Cz-Si:He, H is related to oxygen gettering on defects. Probably it

Fig. 4. Depth profiles of hydrogen and oxygen in Cz-Si:H samples, as-implanted and annealed at 720 K- 10^5 Pa for 0.5 h.

Fig. 5. Depth profiles of hydrogen and oxygen in Cz-Si:H samples, annealed/treated at 920 K- 10^5 Pa and 920 K-1.2 GPa for 0.5 h.

occurs mostly at the surface of initially He- or H-filled clusters and bubbles. Under HT-HP, more numerous but smaller size clusters are formed. The gettering activity is increasing with HP.

Most probably, the oxygen accumulation in the Cz-Si:H samples subjected to short-time anneals at 720–870 K- 10^5 Pa originates from increased diffusivity of oxygen in the presence of hydrogen [5]. The oxygen gettering was negligible in HP-HT treated Cz-Si:H. It

means that HP affects strongly oxygen diffusivity; oxygen mobility decreases dramatically with HP. From comparison of oxygen depth profiles for Cz-Si:He and Cz-Si:H, implanted with comparable He and H doses (hence, with similar extent of damage near R_p) and treated at > 1000 K it follows also that the HP effect on the resultant defect structure of Cz-Si:He and Cz-Si:H is different. Both the annealed and HT-HP treated Cz-Si:He samples exhibit gettering activity at > 1000 K, while the HT-HP processing of Cz-Si:H results in some specific structural changes in implantation-damaged areas. The implantation damaged area of HT-HP treated Cz-Si:H ceases to be active in respect of the oxygen accumulation.

In summary, this paper demonstrates an appearance of the enormous effect of oxygen segregation within the damaged volume. In order to realise the magnitude of this phenomenon, let us consider the integral of the oxygen peak formed as a result of the implantation and the HT-HP treatment of Cz-Si:He (Fig. 2, solid circles). Here oxygen content amounts to about 10^{16} cm^{-2} . This would correspond to the oxygen contained in the Cz-Si slab of about $100 \mu\text{m}$ thickness. Taking the existing data for oxygen diffusion in Si, such extended transport within the semiconductor can be excluded. An alternative source of oxygen to be eventually gettered in the vicinity of R_p would be the oxygen contamination of the

ambient gas. However, even in such a case the transport from the surface would be enormous.

So further investigation is definitely needed to solve that question.

Incorporation of oxygen or di-hydrogen in silicon monovacancy: spin-resonance study of defect excited state

T. Mchedlidze*, N. Fukata, M. Suezawa

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan

Abstract

We attempted to detect changes in an ESR signal from the excited triplet state of a vacancy oxygen pair in FZ-Si samples caused by doping with hydrogen or deuterium prior to electron irradiation. The presence of vacancy-di-hydrogen (vacancy-di-deuterium) complexes in the doped samples was confirmed by the analysis of infrared absorption spectra. Complete similarity of the parameters and shape of the spectra in the doped samples to that in the reference FZ-Si and Cz-Si samples proves that the signal originates from the same defect for all the cases. Further investigations showed that carrier recombination conditions in the sample and numerous hardly controllable experimental settings affect the shape and intensity of the ESR signal, impeding the correct interpretation of the signal origin. © 2001 Elsevier Science B.V. Keywords: Si; O; H; Vacancy; ESR; SDR

1. Introduction

Various hydrogen-containing complexes in Si have long attracted considerable attention [1–3]. The structure and properties of some of these complexes have been established, while others still remain under investigation.

The attribution of the observed HVH optically detected magnetic resonance (ODMR) spectra [4,5], to an excited state of the vacancy-di-hydrogen (VH_2) complex in Si has been questioned [6] based on its similarity to the ESR SL1 spectra which is caused by an excited triplet state of vacancy–oxygen pair (VO^*) [7]. No final conclusion has been reached on the origin of the HVH spectra [8,9]. The main arguments supporting the possible VH_2 origin of the HVH spectra are the change in the shape of resonance peaks upon substitution of hydrogen (H) doping by deuterium (D) doping and the difference in the annealing properties between the vacancy–oxygen pair and the defect responsible for the HVH spectra.

The SL1 signal has several distinctive features. The presence of absorption and emission-related resonance peaks in the SL1 spectra, so-called double-signed spectra, signifies the involvement of a relevant defect in the carrier recombination process [7,10]. The SL1 signal can also be detected using spin dependent recombination (SDR) measurement methods [11,12]. The increase in the charge carrier recombination rate in the sample during the spin resonance on the recombination centers causes the appearance of SDR-related resonance peaks. All SDR peaks have similar sign. The overall recombination processes in the sample affect the ESR and SDR SL1 signals, i.e., the existence of other carrier recombination paths in the sample will suppress them. Thus, the SL1 signal can be termed “recombination controlled spin resonance”.

We attempted to determine the origin of spectra observed in Refs. [4–6] and to find the reasons for the contradictory observations.

2. Experimental

We used phosphorus doped FZ-Si ($\rho = 1000 \Omega \text{cm}$) and Cz-Si ($\rho = 10 \Omega \text{cm}$) samples. Sliced samples,

*Corresponding author. Fax: +81-22-215-2041.

E-mail address: teimuraz@imr.tohoku.ac.jp
(T. Mchedlidze).

mechanically and chemically polished, were annealed in quartz capsules filled with H_2 or D_2 or Ar gas at 1300°C for 1 h. After the annealing, samples were quenched by immersion in water. Annealed and as-grown samples were subjected to irradiation with 3-MeV electrons at room temperature with total doses from $d_e = 3 \times 10^{14}$ to $1 \times 10^{17} \text{ e/cm}^2$. The irradiated samples were stored at temperatures below -10°C .

We conducted FT-IR measurements to verify the presence of VH_2 (VD_2) and VO defects [3,13–17] and to estimate the concentration of interstitial oxygen (O_i) in the samples. Optical absorption spectra of the specimens were measured with an FT-IR spectrometer at 4.2 K. The resolution was 0.25 cm^{-1} .

Spin resonance measurements were conducted on a JEOL X-band ESR spectrometer using a TM_{011} mode MW resonator equipped with a continuous helium gas-flow cryostat. The samples were illuminated with interband light during measurements through the window in the resonator. The derivative of MW field absorption with respect to the magnetic field was measured using a lock-in amplifier and magnetic field modulation with an amplitude of 0.2–0.6 G and a frequency of 100 kHz. The measurements were conducted under constant illumination at 10–20 K.

3. Results and discussion

We carried out a careful ESR investigation of the SL1 spectra in as-grown, H or D doped or argon-annealed FZ-Si samples and Cz-Si samples after irradiation. In all cases the spectra can be characterized by Spin-Hamiltonian with the parameters presented in Refs. [6,7]. Moreover, no additional splitting or broadening of lines was detected in the samples doped with H or D. As seen in Fig. 1, the signal shapes for all samples were identical. These results prove that all the observed ESR spectra originate from the (VO^\bullet) . Differing from Stallinga and Nielsen [6], sample preparation procedures used in our investigation were close to those used by Chen et al. [4]. The presence of VH_2 (VD_2) defects in our H (D) doped and irradiated samples was verified by FT-IR measurements. Thus, our results contradict the conclusions made by Chen et al. [4,5] regarding the involvement of H (D) in the defect responsible for the HVH spectra. However, the above results do not answer the main arguments presented in Ref. [9] regarding the observed change in the resonance line shape and annealing kinetics of the relevant defect. We attempted to determine the possible origin of the contradiction.

First, we attempted to compare the concentration of recombination centers in the samples pre-annealed in the various ambient prior to irradiation. We compared the intensity of the SL1 signal, $I(\text{SL1})$ and the strength of IR absorption peak of the VO

Fig. 1. The “0 \Rightarrow -1” ESR transition from the SL1 spectra in irradiated FZ-Si samples. Sample annealing ambient and amplification factors are indicated above the curves (“R” stands for the reference, as-grown sample). Measurement conditions: $B \parallel [110]$, $T_{\text{MEAS}} = 16 \text{ K}$. Inter-band light illumination, $f_{\text{RES}} = 9.06 \text{ GHz}$, $P_{\text{MW}} = 1 \text{ mW}$.

pair, $I(\text{VO})$ in the samples. The normalized ratios $I(\text{SL1})/I(\text{VO})$ for the samples vary in accordance with proportion $\text{Ar}:\text{D}_2:\text{H}_2 \approx 1:0.66:0.46$. This difference can be attributed only to the influence of recombination centers on the SL1 signal intensity. Namely, the overall concentration of recombination centers after irradiation is smaller in the samples pre-annealed in Ar and larger for the H-doped samples. Apparently, the overall concentrations of recombination centers in the H and D doped samples were also different. Our later investigation of defect creation in similar samples proved the above statements [18].

Next, a comparison of the ESR and SDR SL1 signals from the same Cz-Si sample was performed. By increasing the MW power during ESR measurements, it is possible to significantly increase the intensity of the MW electric field component in the volume of a sample. Thus, an effect related to SDR, i.e., change in the absorption of the MW electric field component during spin resonance [12], may be detected. We succeeded in the simultaneous detection of both ESR and SDR-related SL1 signals.

In Fig. 2, the observed spin resonance spectra are presented for a Cz-Si sample irradiated with $d_e = 3 \times 10^{14} \text{ e/cm}^2$ at three different levels of MW power. As seen, with the increase in the MW power, the intensity of the SL1 ESR spectrum with absorption and emission peaks is gradually decreasing, while the SDR SL1 spectrum, with single signed peaks, emerges and increases in intensity. Details of the transformation are presented in Fig. 3a. For the same MW power the width of the SDR related signal is noticeably larger than that of the ESR peak. As a result, a composite peak, much

Fig. 2. The SL1 spectra from irradiated Cz-Si sample ($d_c = 3 \times 10^{14} \text{ e/cm}^2$). MW power and amplification factor are indicated above the curves. Other experimental conditions were same as those indicated in Fig. 1.

Fig. 3. The “0 \Rightarrow -1” ESR transition from the SL1 spectra in the Cz-Si sample. MW power (mW) is indicated above each curve. (a) $d_c = 3 \times 10^{14} \text{ e/cm}^2$, amplification factor = 10; (b) $d_c = 1 \times 10^{17} \text{ e/cm}^2$, amplification factor = 1. Other experimental conditions were the same as those indicated in Fig. 1.

different in shape from the ESR and SDR peaks, may resemble an additional HF splitting of a signal. It is interesting that ESR to SDR transformation does not occur in a similar sample with high d_c , even if it is placed in the same position in the resonator (see Fig. 3b). Measurements revealed that the “onset” MW power value for the transformation increases with the d_c , i.e. with the concentration of recombination centers in the sample. Irradiation dose dependence for the SL1 signal intensity in the Cz-Si samples also differed from that reported for the VO defect [16].

Although the properties of the SL1 signal presented herein deserve further investigation, this obviously exceeds the aims and limits of the present work. However, we can conclude that the observable shape and intensity of the SL1 signal depend on the recombination conditions in the sample, actual position of the sample inside the resonator, MW power, illumination conditions, etc.

Thus, we can explain contradictory observations with respect to the SL1 signal shape [4,6] as being due to the SL1 signal features. Namely, we suppose that the H and D doped samples after irradiation in Ref. [4] had different concentrations of recombination centers, as was the case in our samples. Such a difference, together with hardly controllable experimental conditions, could cause an observed change in the shape of the resonance peak by an admixture of ESR and SDR signal components in the detected ODMR signal [4]. Annealing strongly affects the recombination conditions inside an irradiated sample. Thus, it can be expected that a change in the recombination-controlled SL1 spectra intensity upon sample annealing will significantly differ from the change in VO concentration, as reported in Ref. [5].

In conclusion, a careful analysis of spectral parameters and the shape of the ESR spectra from H or D doped or Ar-annealed and subsequently electron irradiated samples revealed that the signal originates from the excited triplet state of the VO pair in all cases. The shape of the resonance peaks and the intensity of the signal depend on the VO pair concentration, on the carrier recombination conditions inside the sample and on numerous experimental settings. This complicated dependence is the result of the recombination-controlled nature of the SL1 spectra and can be applied to the investigation of recombination processes that take place in the sample.

Thermal donors and radiation-induced defect states in transmutation doped gamma-irradiated silicon

S.I. Budzulyak, Yu.P. Dotsenko, V.M. Ermakov, V.V. Kolomoets*, E.F. Venger

Department of Galvanomagnetic Properties of Semiconductors, Institute of Semiconductor Physics, Prospect Nauki 45, 03028 Kyiv 28, Ukraine

Abstract

Transport phenomena are studied in uniaxially strained transmutation doped γ -irradiated n-Si(P) crystals. It is shown that thermal annealing of the transmutation doped Si results in the generation of different types of thermodonors. Tensorsensitivity mechanisms in highly strained transmutation doped silicon are identified as well. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The neutron transmutation doping of semiconductors is known to provide a higher homogeneity of the impurity distribution within the crystal volume as compared to the method of doping from the melt. Homogeneous doping, in turn, results in a higher reliability of the devices operating on the principles of carrier heating. On the contrary, a heterogeneous current distribution for both crystal volume and p-n junction degrades the device performance because of microplasma appearance. The neutron transmutation doped (NTD) silicon is also characterized by a higher resistance to γ -irradiation. The technology of the neutron transmutation doping involves, as is well known, a high temperature annealing (at $\sim 800^\circ\text{C}$ for 2 h) in order to remove crystal damage induced by slow neutrons. Since the silicon crystals grown by floating zone (FZ) or Czochralski methods contain a substantial concentration of oxygen ($\approx 3 \times 10^{23}$ and $\approx 1 \times 10^{24} \text{ m}^{-3}$, respectively), the high temperature annealing is expected

to result in the generation of high temperature thermodonors.

Detection of the presence of high temperature thermodonors in NTD γ -irradiated silicon crystals is the aim of this work. Note that influence of thermodonors on NTD silicon properties should increase with a decrease of the phosphorus concentration. Therefore, for pure NTD crystals optimization of the technological regimes of neutron transmutation doping is very important.

2. Experimental

Irradiation of pure monocrystalline silicon crystals with slow neutrons was followed by a high temperature annealing $T \approx 800^\circ\text{C}$ for 2 h. A ^{60}Co source was used for γ -irradiation of transmutation doped silicon by relevant doses of γ -quanta at room temperature. γ -irradiation was performed on the samples with attached electrical contacts to prevent annealing of radiation-induced defects during the contact creation. Longitudinal tensorsensitive effect, Hall effect and their temperature dependencies were investigated using an installation for transport phenomena measurements under high uniaxial pressure. Pressure and temperature dependencies of the

transport phenomena were used to reveal peculiarities of tensoeffects for the two types of crystals, NTD and doped with phosphorus from the melt. In order to obtain the ohmic electric contacts to the n-Si specimens the binary eutectic silicon–gold was used. The values of the main parameters of all measured specimens are listed in Table 1.

3. Results and discussion

In Fig. 1, the dependencies of resistivity vs. pressure for the case of longitudinal tensoresistivity (TR) measurements are compared for n-Si doped with phosphorus at the growth and NTD samples. For the former case (sample #1, Table 1), the TR effect is characterized by the saturation at pressure $X \approx 0.76$ GPa (curve 1, Fig. 1) and the following inessential ($\approx 1\%$) linear decrease of resistivity caused by an elastic change of the sample dimensions with pressure. For the NTD n-Si(P) (sample #7, Table 1), the presence of a maximum at pressure $X \approx 0.6$ GPa and the following exponential decrease of resistivity ($\approx 5\%$) in the pressure range 0.6–1.8 GPa is characteristic. These peculiarities of the TR effect in NTD silicon we associate with the strain-induced ionization of thermodonors which appear at high temperature annealing of crystals after neutron transmutation doping. In γ -irradiated NTD crystals (sample #7c, Table 1), the TR effect is characterized by the strain-induced ionization of A-centers (vacancy–oxygen atom [1,2]), which occurs in the pressure range 1.1–1.8 GPa (curve 3, Fig. 1). Note that the strain-induced ionization of the defect levels (P, TD, A-center) leading to a decrease of the crystals resistivity occurs on

Fig. 1. The dependencies of $\rho_X/\rho_0 = f(X)$ longitudinal TRE for n-Si doped by phosphorus at the growth (1—sample 1) and by slow neutrons irradiation (2, 3—samples 7, 7c respectively). $X \parallel [001] \parallel J$; $T = 78$ K; Dose of γ -irradiation (quanta/cm^2): 1, 2—0; 3— 2.1×10^{17} .

Fig. 2. Temperature dependencies of normalized Hall constant (R_T^H/R_{78}^H) for NTD n-Si(P) (1—sample 7NTD; 2–4—sample 7c) and normalized resistivity (ρ_T/ρ_{78}): 5—sample 8a; 6—sample 7c. Uniaxial pressure X (GPa): 0—1, 2, 5, 6; 0.4—3; 0.8—4.

the background of a resistivity increase which depends on the mechanism of intervalley redistribution of electrons. The presence of radiation-induced centers (P, A-centers) and high temperature thermodonors in NTD γ -irradiated silicon and dependence of their energy levels on the pressure is characterized by temperature dependencies of Hall effect (curves 2–4, Fig. 2) which was measured for sample #7cNTD. The presence of all defect levels (P, TD, A-center) is well detected in temperature dependencies of resistivity for the samples with a higher level of doping by electrically active phosphorus impurity (sample #8a, Table 1). At the same time, for crystals with dominant contribution of the acoustic scattering (sample #7c, Table 1) only presence of A-centers is clearly observable on the $\rho(T)$ dependence (curve 6, Fig. 2). Comparison of temperature dependencies of tenso-Hall effect (curves 2 and 3, Fig. 2) shows the full ionization of P impurity occurs at insignificant pressure (0.2–0.4 GPa). The obtained data prove the theoretical calculations of the uniaxial pressure influence the energy level position of shallow donors [3,4].

Even a more sensitive method to detect any deviation of the mechanism of TR effects from the classical mechanism of intervalley redistribution of electrons (Smith–Herring mechanism) is determination of the deformation potential constant (Ξ_u) in silicon [5]. In this case, the dependence of electron concentration ratio in the upper and lower valleys on pressure is determined via the TR effect data measured in a wide pressure region. For nondegenerated crystals, the ratio of electron concentration in the upper valley (n_2) to electron concentration in the lower one (n_1) is expressed as [6]

$$n_2/n_1 = \exp(-\Delta E/kT) \quad (1)$$

where ΔE is the energy splitting of valleys in uniaxially strained crystals.

Since $\Delta E \sim X$, there is a linear dependence of the logarithm of concentration ratio on the pressure for the tensoeffect mechanism caused only by the intervalley redistribution of electrons:

$$\lg(n_2/n_1) \sim X. \quad (2)$$

In accordance with this method, it was determined that only for sufficiently pure silicon crystals doped with phosphorus during growth can one obtain the linear dependence $\lg(n_2/n_1) = f(X)$ (curve 1, Fig. 3). It was also established that the linearity of the dependence $\lg(n_2/n_1) = f(X)$ occurs in such n-Si crystals only in a narrow temperature range (78–100 K) when pressure dependence of the f-scattering is not observed. The obtained data demonstrate that deviation from linearity of the dependence $\lg(n_2/n_1) = f(X)$ takes place for compensated n-Si(P) crystals (sample #5, Table 1) and NTD n-Si(P) (curves 4, and 2, 3, 5, respectively, Fig. 3).

According to comparison of curves 2, 3 and 5 in Fig. 3, the deviation from linearity in NTD silicon increases with the phosphorus concentration decrease that can be attributed in this case to the relative increase in contribution of strain-induced ionization of high temperature thermodonors. We assume that on conditions of approximately equal content of oxygen in

Fig. 3. The dependencies of $\lg(n_2/n_1)$ vs. uniaxial pressure X for silicon crystals doped with phosphorus at the growth (curves 1, 4—samples 1, 5 respectively) and neutron transmutation doped (curves 2, 3, 5—samples 7NTD, 3NTD, 2NTD respectively).

crystals and equal annealing temperature and time, concentration of thermodonors must be approximately equal in all NTD silicon crystals investigated in this work. Note that speed and anisotropy of energy levels shift of defects (P, TD, A-center) in silicon vs. uniaxial pressure are determined by defects structure and their energy levels in the forbidden band. This fact, as shown from analysis of the obtained data, determines the peculiarities of TR effects in highly strained γ -irradiated crystals of NTD silicon.

4. Conclusions

Analysis of TR effect data in NTD γ -irradiated silicon crystals allowed us to determine regularities of influence on the transport phenomena, additional strain-induced ionization of both radiation-induced energy levels (P, A-center) and levels of high temperature thermodonors which are generated in NTD silicon with high oxygen concentration during the annealing. Enhanced contribution of additional strain-induced ionization of thermodonor levels to tensoeffects with decreasing phosphorus concentration is explained by approximately constant concentration of thermodonors in crystals with equal content of oxygen and identical conditions of annealing.

The additional ionization of defect levels with increasing pressure results in a deviation from linearity of the dependence, $\lg(n_2/n_1) = f(X)$. Whereas, linearity of this dependence is determined by intervalley redistribution mechanism (Smith–Herring mechanism), the analysis of dependencies $\lg(n_2/n_1) = f(X)$ in many-

valley semiconductors can be applied for TR mechanism identification in highly strained crystals. The most comprehensive information in terms of determination of tensoresistive effect mechanisms in the NTD γ -irradiated Si crystals as for the determination of dependencies of transport phenomena caused by the presence of various types of defects, was obtained by analysing both temperature and pressure dependencies of resistivity, Hall effect and the ratio of electron concentration in different valleys of the C-band shifted by deformation. It was demonstrated that the tensoeffects mechanism of intervalley redistribution is inherent only for pure n-Si crystals doped by hydrogen-like donors in a narrow temperature range (78–100 K). The analysis of the obtained data testifies that the slope change of the linear part of dependencies $\lg(n_2/n_1) = f(X)$ does not mean the change of magnitude of the deformation potential constant Ξ_u in n-Si crystals doped by various methods.

Abstract

We study the initial steps of oxidation of the Si(1 1 1)-7 × 7 surface through modeling of different chemisorption sites for atomic O: adatom backbonds in faulted and unfaulted halves of the surface cell, and surface dimer bonds. We use ab initio calculations within local density approximation, and realistic simulation unit cells (4 × 2 and 6 × 3). Our results show the faulted adatom backbond to be favored over the unfaulted adatom backbond, and in-dimer insertion to be the stable adsorption site. We also use our results to interpret scanning tunneling microscopy results, and suggest that adatom adsorption is responsible for bright spots in unoccupied states images, while in-dimer adsorption could be related to dark sites. © 2001 Elsevier Science B.V. Keywords: Oxidation; Silicon surfaces; Oxygen adsorption

1. Introduction

Oxidation of silicon surfaces have been extensively studied recently due to the need to understand and control the Si/SiO₂ interface [1]. The initial stages of oxidation are very different for different surfaces, e.g., for the hydrogenated (1 1 1)Si-H or for the clean (1 1 1)Si-(7 × 7) reconstructed surface [2]. The differences may come not only from the presence of hydrogen but also from the different sites the 7 × 7 reconstruction [3,4] offers for oxygen incorporation. While in the (1 1 1)Si-H oxygen incorporation occurs almost exclusively in the surface Si atom backbonds [5], in the case of the Si-(7 × 7) surface incorporation is thought to occur mainly in adatom backbonds [2,6,7]. The basis for this consensus comes from the evidence provided by scanning tunneling microscopy (STM) images of the clean [8] and oxidized [9,10] surface, which clearly show the enhancement of the adatom features upon oxidation, in

the initial stages. The STM images taken with slow oxidation show [9] that the first two features to appear are: bright adatom spots, with a preference of 2:1 for the faulted half of the surface unit cell; and dark spots, which appear exclusively on faulted halves. With increasing oxidation times, and before the surface is fully oxidized, dark sites dominate and faulted halves are completely obscured.

The major controversy concerning the oxidation process concerns the existence [10,11] or not [12,13] of a molecular precursor, a metastable molecular O₂ species that would survive in the surface for a relatively long time, transforming to chemisorbed O in the adatom backbond. Several theoretical works were dedicated to the molecular precursor, focused on the adatom dangling-bond (DB) as the main “harpoon” to anchor an incoming O₂ molecule; the conclusions point always to the higher stability of any configuration that includes an O atom inserted in an adatom backbond [6,14]. It is important to emphasize, however, that all previous theoretical studies of oxidation of the Si-(7 × 7) surface were performed with simplifications of the surface unit cell, containing only the adatom and rest-atom surface

Fig. 1. Top view of the (6×3) cell used to simulate O adsorption on a Si (7×7) surface. For the sake of clarity, we show only the adatoms (larger dark circles), first layer atoms (white circles) and dimer atoms (smaller dark atoms). The corner holes are located on the vertices of the unit cells. The dashed lines separate the faulted (F) and unfaulted (UF) halves of the unit cell.

entities, in the unfaulted half of the unit cell. There was thus no possibility of comparing faulted and unfaulted halves, or to explore the other possible sites. From bulk defect studies, however, it is well known that the reaction of interstitial oxygen with vacancies is exothermic [15]. In the surface, although there are significant differences in environment, this could mean that insertion in the dimer site is energetically favored. On the other hand, simple geometric division of the unit cell

in regions tells us that “dimer regions” cover almost 40% of total area. We here present a theoretical study of atomic oxygen adsorption on the Si(111)- (7×7) surface, based on more realistic simulations which can take into account the differences between adatoms in the faulted and unfaulted surface, and include the surface dimers. Our results confirm that there is a small energy difference favoring backbond adsorption in the faulted half, and that backbond adsorption enhances the adatom feature in STM. We find, moreover, that insertion in the dimer bonds is indeed favored over backbond adsorption. However, this atomic configuration is not directly visible to STM, but could be related to the dark sites in the images.

2. Methodology

We simulate the Si(111)- (7×7) surface by repeated supercells in the slab model. Slabs are H-saturated on the back-surface, and contain six normal Si layers, plus surface layers, which depend on the surface unit cell. We use doubled (2×2) and (3×3) cells (4×2 and 6×3 , respectively, see Fig. 1) in order to isolate electrically and elastically the inserted O atoms. For the (3×3) cell there are two surface layers, with the stacking fault in one half, plus the adatoms, and we have then two adatoms (faulted and unfaulted), dimers and a corner hole. For the (2×2) cells, there are two surface layers plus the adatom, so we have in this case one adatom and one rest-atom; we use different (2×2) cells, one with normal Si coordination and the other with a stacking fault; calculations are also done for 4×2 -H cells, with one rest-atom DB saturated by hydrogen [14].

Calculations are done using ab initio density functional theory in the local density approximation, using the SIESTA code [16], norm-conserving pseudo-potentials [17] and Ceperley-Alder exchange correlation [18]. We use double-zeta local orbitals for the inner layers, and double-zeta plus polarization functions for the surface layers.¹ We relax all but the lowermost layer, starting from the initial theoretical lattice parameter for Si. We use the isosurfaces of $|\Psi|^2$ to interpret STM images [19]. To do that, we integrate $|\Psi|^2$ over the relevant energy region, in this case for the unoccupied states up to +0.5 eV from the Fermi energy.

3. Results and discussion

We study single atomic O insertion in the adatom backbonds, and in the surface dimer, comparing total energy differences in the stable configurations. We do

¹Orbital cutoff equivalent to a confinement energy shift of 0.3 eV; real-space grid equivalent to a cutoff energy of 130 Ry.

Fig. 2. Isosurfaces of $||\Psi||^2$ at equal densities for the clean Si (6×3) cell (b), for the same surface with an O atom in an adatom backbond (a) and with one O atom in a dimer bond (c). The arrows indicate the positions of O insertion in each case.

not study the silanone incorporation in dangling bonds [20], which is known to be less stable [6,21,22]. Incorporation in adatom backbonds is studied in two different environments: in the 6×3 cell, we compare directly faulted and unfaulted subsurface layers, and the environment mimics more closely corner adatoms, since it is flanked by dimers, and faces a corner hole. In the 4×2 cells, we compare energy differences for the clean and oxidized situations, and the environment includes rest-atoms, thus softening the surface layer. We note that the adatom DB occupation in these cells are never equal to the expected value in the 7×7 , but are similar, being $1/12$ higher or lower in the 6×3 and 4×2 -H, respectively.

Our results indicate that there are large lattice relaxations in all cases upon O insertion. Comparing adatom backbond insertion, relaxations are stronger in the 4×2 cells. The adatom actually moves laterally, as also found for regular surface atoms in the (111)Si-H surface [5], and this relaxation is easier in the softer environment of these cells. We find for adatom backbond adsorption that the faulted half is favored over the unfaulted half by ~ 0.05 eV. Insertion in the dimer bond is followed by even stronger relaxation, and releases surface strain energy. Accordingly, the energy gain is larger and dimer insertion is favored over the unfaulted adatom backbond by ~ 0.4 eV.

This result would seem to be in contradiction with STM experiments, insofar as dimer insertion was never

indicated as a possible candidate for STM image features. We show in Fig. 2 a comparison of isosurfaces of $||\Psi||^2$ for the clean 6×3 cell, and for O adsorption in the faulted adatom (results for the unfaulted adatom have similar character), and on the dimer bond. Comparing with Fig. 1, adatom DBs are seen in the first layer, and backbonds and dimer bonds are seen in the second layer from top; so, as expected, STM images of the clean surface would show mostly adatom DBs. What can be clearly seen is that adatom features are enhanced by backbond O insertion, supporting the association of the bright spots in STM images with this type of O adsorption. Furthermore, it is seen that dimer insertion bleaches all features, adatoms included. While O-related “unoccupied charge” distribution can be seen in this energy region for backbond insertion, O inserted in dimers are not visible at all. So, even if the STM tip could reach the second layer, in this bias there would be no states visible (in a previous study of the clean 7×7 surface by Qian and Chadi, it was shown that dimer states should be reached only at $\sim E_F - 2$ – 3 eV). We can thus speculate that the dark spots appearing immediately upon oxidation are related to O insertion in dimer bonds. We need further work to be able to distinguish the effects of dimer adsorption in faulted and unfaulted adatoms.

Summarizing, we find that O adsorption in faulted adatom backbonds are preferred over unfaulted adatom backbonds, and that features related to unoccupied

states of adatom dangling bonds are enhanced by backbond oxidation, supporting this assignment of bright spots in STM. Dimer insertion is favored by ~ 10 kT at room temperature, but seriously depletes all unoccupied states up to $\sim E_F + 0.5$ eV. It is possible that dark spots in STM images are related to dimer adsorption. In this case, our results support the view that oxidation of the (111)Si-(7×7) surface is dissociative, since both bright and dark spots are immediately seen on oxidation.

Defects and their influence on the luminescence of rare-earth ions implanted in single crystal Si

N.A. Sobolev*

Ioffe Physicotechnical Institute, Polytechnicheskaya 26, 194021 St. Petersburg, Russia

Abstract

With respect to the use of (111)-oriented silicon substrates, the modification of structural defects as well as electrically and optically active center spectra in solid-phase epitaxial recrystallized rare-earth doped Si layers has been investigated. TEM and X-ray diffraction revealed the presence of microtwins and dislocations in very high densities exceeding 10^{10} cm^{-2} in (111) Si: (Er,O). The formation of microtwins and dislocations in very high densities in (111) samples enabled us to observe some new effects and improve the characteristics of rare-earth doped Si-based light-emitting diodes (LEDs), in particular, to prepare avalanching and tunneling diodes characterized by uniform breakdown over the whole area of p–n junction and working at room temperature. Temperature enhancement of the rare-earth-related electroluminescence (EL) intensity in (111) LEDs is observed under avalanche and tunnel breakdown of p–n junctions. The enhancement is related to the formation of process-induced deep level centers. New centers emitting under reverse bias and characterized by the highest effective cross section for the excitation of Er^{3+} ions were first observed. The LEDs with EL of Ho^{3+} ions at room temperature have firstly been prepared. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Defects; Ion implantation; Rare-earth doped Si; Light-emitting structures

1. Introduction

Light-emitting structures based on Er-doped monocrystalline Si have attracted considerable interest for optoelectronic applications. To produce such structures, Polman with co-authors [1] suggested to use the solid phase epitaxial (SPE) technique. In the case of conventional dopant ions, the implantation is carried out in (100)-oriented substrates at room temperature. SPE recrystallization of layers amorphized by the Er-ion implantation under these conditions is followed by the formation of end-of-range defects and hairpin dislocations, which may be responsible for a relatively low intensity of Er-related luminescence. To prevent the structural defects formation, Franzo et al. [2] suggested implanting Er ions at 77 K. It allowed them to prepare light-emitting diodes (LEDs) which demonstrate a high intensity of Er-related electroluminescence (EL) under

tunneling breakdown of the p–n junction at room temperature. To prevent the hairpin dislocation formation, we suggested to implant Er ions into (111)-oriented substrates at room temperature some years ago [3]. The purpose of this paper is to review our recent results demonstrating the possibilities of the modification of the SPE technique for the engineering of structural defects and electrically and optically active centers as well as improvements of luminescence properties of rare-earth doped Si-based LEDs.

2. Experimental

Er was introduced into $5 \Omega \text{ cm}$ (111)- and (100)-oriented n-Cz–Si wafers with a double implant of 2.0 and 1.6 MeV ions at room temperature. The samples were implanted to a dose of 1×10^{14} , 3×10^{14} or $9 \times 10^{14} \text{ cm}^{-2}$, and the doses for each pair of implants were identical. To enhance the luminescence response,

*Tel.: +7-812-24-73885; fax: +7-812-24-71017.

E-mail address: nick@sobolev.ioffe.rssi.ru (N.A. Sobolev).

oxygen ions were coimplanted at 0.28 and 0.22 MeV energies, and implant doses were one order of magnitude larger than the erbium doses used. The oxygen implant energies were chosen such that their projected ranges matched those of the Er implants. To fabricate Si:(Ho,O) LEDs, the co-implantation of Ho ions into (111) n-Cz-Si at 2.0 and 1.6 MeV energies and $1 \times 10^{14} \text{ cm}^{-2}$ dose as well as of oxygen ions at 0.29 and 0.23 MeV energies and $1 \times 10^{15} \text{ cm}^{-2}$ dose was carried out at room temperature. The implantation produced a continuous amorphous layer extending from the surface to a depth of $\sim 0.7 \mu\text{m}$. Annealings were made in a chlorine-containing atmosphere at 620°C for 1 h to induce the SPE recrystallization of the amorphous layer and at 900°C for 0.5 h to produce optically active Er- and Ho-related centers and reduce the density of regrowth defects. The $p^+ - n^-$ junction was produced by 40 keV boron implantation at a dose of $5 \times 10^{15} \text{ cm}^{-2}$ into the front side of the wafer. The back side was implanted with phosphorus at 80 keV and a $1 \times 10^{15} \text{ cm}^{-2}$ dose. Titanium and gold sputtering, photolithography, as well as chemical etching, were performed to prepare LEDs with a mesa-like edge contour. SIMS, RBS, TEM, X-ray diffraction, transient-stimulated capacitance, capacitance-voltage, photoluminescence (PL) and EL techniques were used to study the properties of Si:(Er,O) structures. Structural, electrical and optical properties in Ho and O ion co-implanted Si were also studied to determine some details of defect formation and luminescence processes.

3. Results

TEM and X-ray diffraction techniques were used to study the microstructure of (111) Si:(Er,O) [4]. TEM showed that the SPE-regrown layer consists of at least two sublayers. The $0.2 \mu\text{m}$ -thick sublayer lies at the bottom of the regrown layer and contains small loop-like defects of high density (so-called end-of-range (EOR) defects). The $0.6 \mu\text{m}$ -thick sublayer spreads from the band of the EOR defects to the wafer surface. Its defect structure is more complex and consists of microtwins and dislocations. TEM and X-ray diffraction revealed that numerous microtwins formed on the (111) planes parallel and inclined to the surface are observed over the entire upper sublayer. The twins were found to be platelets with lateral dimensions of 15–30 nm and a thickness of about 2–9 nm, and their densities throughout the regrown layer were nonuniform. Dislocations form a dense spatial network propagating through the upper sublayer. The dislocation lines are rather highly curved than being linear. It does not allow us to identify them as hairpin (V-shaped) dislocations, which are observed in (100) Si layers recrystallized by SPE following amorphization using Si and Er ions. The

curvature of the dislocation lines can be due to the interaction between the dislocations and microtwins. The dislocation densities observed in the regrown layers were very high, with densities exceeding 10^{10} cm^{-2} . Within the implant fluence range studied, between 1×10^{14} and $9 \times 10^{14} \text{ Er/cm}^2$, the twin and dislocation densities were observed to increase with fluence, while the twin dimensions were found to decrease. The changes in the spectrum of structural defects in (111) samples, as compared with the (100) sample spectrum, allowed us to observe some new effects and improve the characteristics of LEDs. On the basis of (111) structures, we have prepared avalanching and tunneling diodes (ADs and TDs).

The first (111) ADs and TDs have been investigated in Refs. [3,5], respectively. The EL spectra of the reverse-biased samples contain a sharp luminescence line at a wavelength of $\lambda \sim 1.538 \mu\text{m}$ accounted by intra-4f shell transitions of Er^{3+} ions and a relatively weak radiation, practically independent of the wavelength. This radiation was observed in both avalanche and tunnel breakdown due to intraband transitions of hot carriers in Si. Fig. 1 shows the temperature dependence of the EL intensity at $\lambda \sim 1.538 \mu\text{m}$ (curve 2) in AD. An enhancement of the Er-related EL intensity takes place. On the contrary, a weak temperature quenching of the EL intensity takes place in (100) Si:(Er,O) diodes [2,6] (Fig. 1, curve 1). Capacitance spectroscopy measurements showed that the unusual temperature dependence of the EL intensity under fixed reverse current is related to the formation of deep level centers (hole traps) in the lower part of the forbidden gap [3]. The effective concentration of the traps are several times higher than the ionized center concentration in the space charge layer before the diode was switched into the breakdown regime. The non-exponential character of the measured capacitance decay may be related to the existence of several levels with different ionization energies or the zone of traps in the lower half. We suggest that the process-induced dislocations are responsible for the

Fig. 1. Temperature dependence of rare-earth-related EL intensity in ADs and TDs at reverse bias in: 1—(100) Si:Er:O AD [6], 2—(111) Si:Er:O AD [3], 3—(111) Si:Er:O TD [7], and 4—(111) Si:Ho:O AD [10].

levels. The drop of Er^{3+} -related EL intensity, as the temperature decreases from 190 to 150 K (Fig. 1, curve 2), is associated with the smaller width of the space charge layer and the respective decrease in the concentration of Er-related centers which may be excited. The tunneling (111) LEDs have been investigated in Refs. [5,7]. Fig. 1 (curve 3) shows the temperature dependence of the EL intensity at $\lambda \sim 1.538 \mu\text{m}$ [7]. A temperature enhancement of the Er-related EL intensity also takes place.

The EL intensity as a function of the reverse current density passing through the diode can be described by solving the rate equation accounting for the excitation and deexcitation processes of Er^{3+} ions:

$$dN^*/dt = \sigma j(N - N^*)/q - N^*/\tau, \quad (1)$$

where N and N^* are the total and excited amount of Er ions, σ is the effective cross section for excitation, τ is the lifetime of the excited state $^4\text{I}_{13/2}$, j is the current density passing through the p-n structure, and q is the electron charge. The EL intensity is proportional to N^*/τ_{rad} , where τ_{rad} is the radiative lifetime of Er^{3+} ions. At steady state, solving Eq. (1) gives the dependence

$$\text{EL}(j)/\text{EL}_{\text{max}} = (\sigma\tau j/q)/(\sigma\tau j/q + 1), \quad (2)$$

where EL_{max} is the maximum EL intensity. From a fit to the data measured in Ref. [8], we have obtained $\sigma\tau = 8.7 \times 10^{-20} \text{ cm}^2 \text{ s}$ at 300 K. This value is one order of magnitude higher than that obtained by the authors in Ref. [9] for tunneling (100) diodes. Er-related EL intensity saturation achieved under the avalanche regime at current density is one order of magnitude lower than that under the tunnel regime. In order to separate the contribution of the excitation and deexcitation processes in the increase of $\sigma\tau$ values, it is possible to make independent measurements of the cross section σ and lifetime τ . The EL transient during the diode turn-on is described by solving Eq. (1) as

$$\text{EL}(t)/\text{EL}_{\text{max}} = [(\sigma\tau j/q)/(\sigma\tau j/q + 1)] \times \{1 - \exp[-(\sigma j/q + 1/\tau)t]\}. \quad (3)$$

The EL signal approaches the steady state with a characteristic time τ_{on} given by

$$1/\tau_{\text{on}} = \sigma j/q + 1/\tau. \quad (4)$$

According to Eq. (4), the dependence of $(1/\tau_{\text{on}})$ on the reverse current is linear. Its slope is proportional to the excitation cross section of Er^{3+} ions, σ , and its intersection with the ordinate axis is equal to the reciprocal of the lifetime of the Er^{3+} excited state $(1/\tau)$. Fig. 2 (curve 2) shows $1/\tau_{\text{on}}$ as a function of reverse current for AD [8]. A fitting of the experimental time dependencies of EL intensity rise at different current densities with Eq. (4) has given $\sigma = 2.3 \times 10^{-16} \text{ cm}^2$ and $\tau = 380 \mu\text{s}$ at 300 K [8]. An increase of σ and τ by ~ 3.8 times as compared with the

Fig. 2. Reciprocal time constant of EL intensity rise (τ_{on}) vs. the difference in the operating (j) and threshold (j_{th}) reverse current densities for centers studied in Si:Er:O ADs and TDs; 1—(100) TD [9], 2—(111) AD [8], 3-1 and 3-2—(111) TD [5].

corresponding data measured in tunneling diodes (Fig. 2, curve 1, $\sigma_{\text{tun}} = 6 \times 10^{-17} \text{ cm}^2$ and $\tau_{\text{tun}} = 100 \mu\text{s}$ [8]) takes place. The higher excitation efficiency under the avalanche regime than that under the tunnel breakdown may be due to a change of the energetic spectrum of hot carriers at the changes of the breakdown mechanisms.

The study of the kinetics of EL intensity when the reverse current is turned on in (111) TDs shows that the same kind of Er-related light-emitting centers is introduced in (100) TDs as well as in (111) ADs and TDs (Fig. 2, curves 1, 2 and 3-1). In (111) tunneling LEDs, we have also observed the formation of new kind of centers emitting under reverse bias (Fig. 2, curve 3-2). These centers are characterized by the highest $\sigma \sim 7 \times 10^{-16} \text{ cm}^2$. Such diodes exhibit the shortest characteristic rise time for Er-related EL in Si:(Er,O) LEDs.

The main physical relationships established in defect formation and luminescence in (111) Si:(Er,O) samples enabled us to prepare the first LEDs with EL of Ho^{3+} ions at room temperature [10]. The EL related to the internal 4f-shell transitions of Ho^{3+} ions from the first excited state ($^5\text{I}_7$) to the ground state ($^5\text{I}_8$) is observed at 300 K in the range from 1.9 to $2.2 \mu\text{m}$ [10]. The maximum intensity of the Ho-related EL in Si:(Ho,O) takes place at $\sim 1.96 \mu\text{m}$. Fig. 1 (curve 4) shows the temperature dependence of the EL intensity at $\lambda \sim 1.96 \mu\text{m}$ [10]. A temperature enhancement of the Ho-related EL intensity is also observed.

The comparison of the experimental data concerned with the structural defects and optical properties of (111) Si:(Er,O) and Si:(Ho,O) LEDs invites us to suppose that electrically and optically active centers belong to the complexes formed near the dislocations

and containing rare-earth ions and intrinsic point defects.

4. Summary

The use of the (1 1 1)-oriented substrates enabled us to modify spectra of structural defects, electrically and optically active centers. The effect of temperature enhancement of the Er- and Ho-related EL intensity is associated with the formation of deep level centers introduced in the lower part of the forbidden gap. The new Er-related light-emitting centers have been observed. They are responsible for the shortest-ever-recorded characteristic rise time for Er-related EL in LEDs under breakdown conditions.

Abstract

Previously, we reported on the enhancement of Er photoluminescence (PL) in silicon upon mid-infrared (MIR) laser pulse fired at certain delay with respect to Nd:YAG pulsed primary excitation. This effect was explained as the ionization of traps by the MIR beam. The shallow nature of the traps was concluded from its temperature and wavelength dependence. In this contribution, we have studied temporal characteristics of the enhancement effect as a function of the delay time between the two pulses. Decay kinetics of erbium PL measured at 4 K was found to show two different time constants of 1 ms (fast) and 26 ms (slow). A correlation between the enhancement effect and the amplitude of the slow component of the Er PL has been observed. We also have noticed that the enhancement of Er emission is accompanied by subsequent quenching of the slow component, indicating redistribution of energy in the system. Based on the study, we conclude that MIR laser ionizes non-equilibrium traps whose thermalization is responsible for the slow component of the Er PL. © 2001 Elsevier Science B.V. Keywords: Erbium; Photoluminescence; Free electron laser

1. Introduction

Research on crystalline silicon doped with erbium has been performed in the last decade due to its importance for telecommunication. During the last years scientists tried to obtain efficient room temperature Er^{3+} luminescence by co-doping with oxygen in Si [1] or co-doping with Yb and Si nanocrystals in SiO_2 [2], but the excitation mechanism remains under dispute. Experimental data are usually based on experiments of amplitude and kinetics of Er PL under steady state conditions as a function of temperature. Unfortunately, many processes can be simultaneously activated while increasing temperature, so a new kind of approach has to be considered. A two-beam experiment performed at 4 K and done at the Dutch free electron laser facility (FELIX) offers such a possibility. In this case, we can

selectively induce individual transitions optically instead of thermally, making the system very attractive for spectroscopic studies. As a result of sample illumination by the first beam (pulsed frequency doubled Nd:YAG), the Er^{3+} characteristic transition at $1.54\text{ }\mu\text{m}$ is observed. The MIR pulse fired at certain delay can produce both enhancement and quenching of the Er PL. Temporal analysis of these effects is presented in this work. A set of rate equations to model our results will also be discussed.

2. Experimental

For details of the experimental set-up for two-beam experiments in the MIR, see for example Ref. [3]. In this study, several different crystalline silicon samples implanted with erbium and oxygen ions were investigated. While the amplitude and temporal characteristics of the MIR-induced enhancement effect showed some variation in different materials, the general features were

*Corresponding author. Tel.: +31-20-525-5644; fax: +31-20-525-5644.

E-mail address: manuef@science.uva.nl (M. Forcales).

common in all samples. The particular experimental data presented here for illustration of the results were obtained for a sample prepared from Czochralski-grown silicon implanted with Er at a dose of 10^{13} cm^{-2} and co-implanted with oxygen. The implantation was followed at 900°C annealing during 30 min.

3. Results and discussions

An illustration of the MIR-induced enhancement effect is shown in Fig. 1 for different delays. Extra PL identified uniquely as erbium emission initially grows, then reaches its maximum and finally decreases on a time scale of tens of milliseconds. Temporal characteristics of the MIR-induced enhancement effect are shown in the inset of Fig. 1. A time rise (τ_{rise}) of 1 ms is observed while a much longer component (τ_{decay}) around 26 ms is identified for the decay. Measurements done at low Nd:YAG pumping intensities [4] showed a maximum enhancement effect of Er PL for very short delays ($\tau_{\text{rise}} = 0$). If we consider saturation of the Er PL, it seems logical that additional excitation is only possible when Er^{3+} luminescence is outside saturation regime. Er kinetics at $1.54 \mu\text{m}$, as presented in Fig. 2, cannot be fitted with a single exponent that has a time constant of 1 ms (τ_{Er}). A double exponent is necessary to fit the signal in the whole range. It is interesting to notice that we can fit the slow component of Er PL kinetics (τ_{D}) using the value of τ_{decay} .

Although it is not clear from Fig. 1, enhancement is accompanied by a subsequent quench of the slow Er PL component. By scanning the MIR photon quanta energy for the enhancement and quenching amplitude, identical wavelength dependence are obtained. We therefore conclude that both effects are related to ionization of the same levels. In order to determine when the Er PL enhancement and quenching disappear, we performed

Fig. 1. Normalized Er PL kinetics at 4 K. MIR-induced Er PL enhancement effect for different delay times. As can be seen in the inset, the MIR-induced Er PL enhancement grows with τ_{rise} (1 ms) and disappears with τ_{decay} (26 ms).

Fig. 2. Normalized Er PL kinetics at 4 K for high Nd:YAG pump intensities. The signal cannot be fitted with a single exponent τ_{Er} ($= \tau_{\text{rise}}$). A double exponent with τ_{Er} and τ_{D} is necessary to fit the complete kinetics.

Fig. 3. Normalized Er PL kinetics for different temperatures. At $T = 20 \text{ K}$, the slow component is quenched after the enhancement, while at 40 K the slow component is no longer available so no enhancement is induced by the MIR pulse.

temperature dependence measurements. In Fig. 3, the normalized amplitude at $1.54 \mu\text{m}$ is plotted for different temperatures. Above 50 K both the effects disappear. A closer look at the low temperature kinetics revealed that the enhancement is only possible when the slow component is available.

Based on these results, the following model with a schematic illustration in Fig. 4 is proposed. We consider the dynamic population via a set of rate equations in which erbium (N_{Er}) and defect centers or traps (N_{D}) are excited by capturing excitons (N_{ex}) with a different absorption cross sections (σ_i) and with the possibility of saturation for both processes:

$$\frac{dN_{\text{ex}}}{dt} = G\delta(t) - \frac{N_{\text{ex}}}{t_0},$$

$$\frac{dN_{\text{Er}}}{dt} = \sigma_1 N_{\text{ex}} (N_{\text{total}}^{\text{Er}} - N_{\text{Er}}) - \frac{N_{\text{Er}}}{\tau_{\text{Er}}},$$

where G is the exciton generation term and t_0 is the effective decay time of the excitons. Solving the rate

Fig. 4. A model to explain MIR-related enhancement and quenching of the Er PL. For explanation see text.

equations leads to an exponential decay of $N_{\text{Er}}(t)$ and $N_{\text{D}}(t)$. At the time when the FEL pulse is triggered (t_{FEL}) only ionization of traps occurs because they are shallow enough to be ionized by the MIR photon quanta energy (70–170 meV). The Er excited state population remains unaffected, basically because the Er-related center has already transferred its energy to Er^{3+} . From t_{FEL} , we can consider the same system of rate equations, but taking G_{FEL} as the new generation term, proportional to the concentration of traps at the time when the FEL is fired: $N_{\text{D}}(t_{\text{FEL}})$. In this way, a good description of the experimentally measured enhancement effect is obtained.

We will now address the microscopic nature of the slow $\tau_{\text{D}} \approx 26$ ms component appearing at $1.54 \mu\text{m}$ PL and spectroscopically proved to be Er emission. We identify it as being due to excitation of Er ions by thermal emission from the non-equilibrium traps. These traps are populated by the Nd:YAG pump pulse and while returning to equilibrium will thermally emit carriers, which can then recombine exciting Er ions. Since the time constant of thermal emission exceeds the

Er relaxation time (at 4 K), this slow excitation process will be directly reproduced in the kinetics of the Er-related PL signal [4]. Alternatively, carriers localized at these traps can be rapidly ionized by the FEL, resulting in an abrupt increase of the Er PL. A support of this model is obtained from the temperature dependence of the MIR-induced enhancement. As the temperature is increased, the thermal emission from traps becomes more efficient (and faster, for example at 50 K can be in the order of a nanosecond). The slow component of the Er PL vanishes and the enhancement effect is no longer possible.

4. Conclusions

Following all the results presented in this paper, we conclude that the MIR-induced enhancement effect is the result of excitation of erbium ions by free carriers released by the MIR from non-equilibrium traps available in the host silicon. Simultaneously, we can naturally explain the quenching effect induced optically by the MIR, as the ionized traps can no longer provide for a slow excitation mechanism of Er by their thermalization. From temperature dependence, we have found out that both effects disappear simultaneously above 50 K, so we conclude that the traps responsible for optical storage are shallow.

Abstract

A successful observation of Zeeman effect on Er^{3+} -related photoluminescence in silicon is reported. In a sublimation MBE-grown Si/Si:Er superlattice, a clearly resolved splitting of major spectral components was observed in magnetic fields up to 5.5 T. The Zeeman effect was also investigated for the “hot line” appearing in the spectrum upon temperature increase. Based on the preliminary analysis of the data, the symmetry of the center responsible for the dominant emission line is identified as orthorhombic C_{2v} . Other spectral components originate from at least two more optically active, Er-related centers simultaneously present in the same sample. One of them most probably has cubic T_d symmetry. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Photoluminescence; Rare-earth ions; Zeeman effect

1. Introduction

Erbium in various host crystals gives rise to the characteristic emission at $\lambda \approx 1.54 \mu\text{m}$, due to the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transition of the Er^{3+} ion. Since this particular wavelength is very nearly coincident with the absorption minimum of glass fibers used for telecommunication networks, erbium doping of semiconductors attracts considerable attention. The Si:Er system is of special interest in view of the highly successful and versatile silicon technology. As a result of a continued research effort, Si:Er-based devices, such as light emitting diodes and optical amplifiers, have been successfully developed. In contrast to that, many of the more fundamental aspects of the Si:Er system lack yet satisfactory understanding. In particular, the microstructure of the optically active Er center in silicon is not known.

For Er-doped GaAs, a combination of special growth techniques [1] and spectroscopic investigations [2–4] allowed the microscopic models of two different optically active centers to be proposed. In case of Si:Er, the situation is complicated due to a multiplicity of Er-related centers; more than 100 emission lines have been identified in a high-resolution infrared absorption study on Er-implanted Si [5]. These were assigned to emissions from several, simultaneously present Er-related centers. Moreover, again in contrast to GaAs:Er, but also to, e.g., GaN:Er, individual centers could not be separated by excitation spectroscopy, indicating an (equally) strong lattice coupling of all the species. Prominent formation of cubic center was shown by channeling experiments [6], which identified an isolated Er ion at a tetrahedral interstitial site as the main center generated in crystalline silicon by Er implantation. The channeling studies could not, however, conclude on optical activity of an isolated Er interstitial. Electron paramagnetic resonance has not been, so far, successful in identification of optically active Er-related centers in Si [7]. Also, attempts to observe the Zeeman effect in photolumines-

E-mail address: nguyen@science.uva.nl (N.Q. Vinh).

cence (PL) of Si:Er were disappointing. Due to the earlier mentioned inhomogeneous character of the line width, application of magnetic field results in broadening and subsequent vanishing of emission lines.

2. Experimental

The recently developed sublimation MBE technique offers new possibilities to develop high quality Si:Er structures. The sample used in the current study has been prepared by this technique and features a quantum structure of 400 interchanged Si and Si:Er layers of a few nanometers thickness. Following the 30 min anneal at 800°C, PL emission from such a sample is at least an order of magnitude more intense than for usual materials prepared by ion implantation. Photoluminescence spectrum at $T = 4.2$ K, depicted in Fig. 1, contains only a few lines of a very small width: $\Delta E \approx 10 \mu\text{eV}$. Upon temperature increase, also shown in the figure, a higher energy “hot line” appears. It corresponds to a transition from a higher lying multiplet of the $^4I_{13/2}$ excited state. Based on the crystal field analysis, predominant formation of a single type of center, labeled Er-1, has been proposed [8,9]. In what follows we will present results of the magneto-optical spectroscopy on this material.

Experiments were performed at liquid-helium temperature using a cw Ar⁺-ion laser operating at 514.5 nm for sample excitation. The sample was placed in a split-coil superconducting magnet with optical access (Oxford Instruments Spectromag 4), providing magnetic fields up to 5.5 T. The emerging luminescence was dispersed by a high-resolution 1.5 m F/12 monochromator (Jobin Yvon THR-1500, equipped with a 600 grooves/mm grating blazed at 1.5 μm , and detected with a liquid-nitrogen cooled Ge detector (Edinburgh Instruments)). For

polarization measurements, a quarter-lambda plate and a linear polarization filter were used. The Zeeman effect was observed with magnetic field parallel to the $\langle 011 \rangle$ and $\langle 100 \rangle$ crystallographic directions of the sample, the latter one being also the stacking direction of the multilayer structure. The experimental configuration permitted the observation of the luminescence along and perpendicular to the field direction.

3. Results and discussion

In the crystal field of cubic symmetry, the $^4I_{15/2}$ ground and the $^4I_{13/2}$ lowest excited states split in two doublets (Γ_6 and Γ_7) and three quartets (Γ_8), and three doublets (Γ_6 and Γ_7) and two quartets (Γ_8), respectively. The lower symmetry crystal field splits the remaining quartets into doublets. Let us now consider transitions between two Kramers doublets (belonging to a particular configuration of a center of a not defined symmetry). In the magnetic field B , we should observe a splitting of the emission line into four components corresponding to two $\Delta M_J = 0$ (which are linearly polarized), and two $\Delta M_J = \pm 1$ circularly polarized transitions. These will appear at the field dependent energies:

$$h\nu_{1,2}(B) = h\nu(0) \pm \frac{1}{2}(G - g)\beta B$$

and

$$h\nu_{3,4}(B) = h\nu(0) \pm \frac{1}{2}(G + g)\beta B,$$

where G and g are the effective g -factors of the lower and upper doublet, respectively. In the experiment, we conclude that neither of the lines split off by the magnetic field shows any circular polarization. This indicates that we deal mostly with electric-dipole-type transitions, without spin flips. This is to be expected for Er, since the strong spin-orbit coupling, characteristic for the rare-earth ions, leads to the admixture of different excited configurations (with different L and S quantum numbers but the same J) to the 4I_J multiplets. In consequence, the linearly polarized $\Delta M_J = 0$ transitions are usually orders of magnitude stronger than the circularly polarized $\Delta M_J = \pm 1$ transitions. In the magnetic field, we should expect to see only transitions without a change of the effective spin.

The transition probabilities for the two lines are equal, since they involve Kramers conjugate states. Any difference in the PL intensities reflects the difference in the population of the magnetic field split states of the upper doublet. In principle, if the spin lattice relaxation time is much shorter than the radiative lifetime, one should be able to determine the g -factor of the upper doublet by comparing the line intensities as a function of B at constant temperature. Unfortunately, at 4.2 K, this is not the case. Studies of the temperature dependence at

Fig. 1. PL spectrum of the multilayer Si/Si:Er structure used in the current study, as observed at two different temperatures. Individual lines are labeled as used in the text.

4.5 T show that the population of the upper split state decreases with increasing temperature at low temperatures—since the relaxation time is temperature dependent—and only above 30 K the thermalization is really fast enough to obtain any reliable g -factors.

Figs. 2(a) and (b) show the magnetic field-induced splitting of the strongest PL line (marked 1 in the spectrum depicted in Fig. 1) for $B \parallel \langle 100 \rangle$ and $B \parallel \langle 011 \rangle$ configurations. As can be seen, line 1 splits in the magnetic field into three components for $B \parallel \langle 100 \rangle$ and five components for $B \parallel \langle 011 \rangle$. The position of one of them, in both field orientations, almost does not move with the magnetic field strength—for this line, the effective g -factors of the upper and lower state must be almost equal. Assuming that all lines stem from one kind of center and there is no accidental overlap of two PL lines from centers of different symmetry at $B = 0$, we have to consider a low symmetry center with different orientations of the g -tensor axes of the possible configurations with respect to B direction. Naturally, each observed component would then involve transitions between two Kramers doublets.

Cubic T_d or trigonal C_{3v} symmetries cannot explain the observed splitting. It corresponds, however, very well to the orthorhombic $I(C_{2v})$ symmetry type. The number of lines and their relative intensities reflect the expected 2:1 for $\langle 100 \rangle$ and 4:1:1 for $\langle 011 \rangle$. Unfortunately, at this stage of research, due to the lack of experimental data at other field orientations (e.g., $\langle 111 \rangle$) individual g -factors of the upper and lower doublet cannot be uniquely determined.

The C_{2v} symmetry is also consistent with the magnetic field-induced splitting of the “hot line”. However, since also in this case we are dealing exclusively with $\Delta M_J = 0$

transitions, individual g -tensors of the involved states cannot be separated. Even assuming that the “hot line” belongs to the same center as line 1, which is a reasonable assumption, we can come up with different sets of g -factors giving an equally good fit. From numerical analysis, we can only conclude that one of the g -tensor values of the lower doublet must be close to zero.

The same C_{2v} symmetry type is also observed for line 4. We conclude, therefore, that lines 1, 4 and the “hot line” could correspond to the same center.

Lines 2 and 3 behave quite differently to lines 1, 4 and the hot line. For B along $\langle 100 \rangle$, line 2 splits into three symmetrical pairs. It cannot stem from transitions between two Kramers doublets of whatever symmetry, and there must be at least one quartet state involved. Since, for $B \parallel \langle 011 \rangle$ similar three pairs of lines are seen, the center seems to have a high symmetry, however, the number of lines is puzzling (for transitions between a cubic quartet and a doublet four lines are expected). At high magnetic fields (above 4 T), the line positions do not depend linearly on B any more and start to curve up to higher energies (especially the lower energy lines). Clearly, there appears to be some interaction between the involved states. One possible explanation is that we deal with a center of cubic symmetry which has a close lying doublet and quartet state in the excited state and a doublet in the ground state (or vice versa). There is no doubt that line 2 does not belong to the same center as line 1.

Line 3 splits into four pairs at $B \parallel \langle 100 \rangle$ and six pairs for $B \parallel \langle 011 \rangle$. It is clearly lower than the cubic site symmetry and must involve transitions between more than two doublets. The situation is clearer than for line

Fig. 2. Magnetic field-induced splitting of line 1 for (a) $B \parallel \langle 100 \rangle$ and (b) $B \parallel \langle 011 \rangle$ configuration.

2. From the analysis of the data, we conclude that there are two doublets in the excited state separated by about 3 cm^{-1} .

4. Conclusions

Based on the preliminary analysis of the Zeeman effect data, we conclude that the individual components of the Er-I PL spectrum originate from more than one (possibly three) different Er-related optically active centers. The symmetry of the most prominent one is tentatively identified as orthorhombic $I(C_{2v})$. At least one of the remaining spectral components corresponds to a cubic center (T_d). All the observed PL lines are due to electric dipole-induced transitions without spin flips. Therefore, precise determination of g -tensors at this moment is not possible.

In the continuation of the project, we will investigate Zeeman effect for an arbitrary field orientation, i.e., not along the main directions, where also circularly polarized $\Delta M_J = \pm 1$ transitions should appear. We will look carefully at the intensity changes of individual components at a higher temperature range $T > 30\text{ K}$, as induced both by temperature and field increase. In this

way, we hope to obtain independent information on Zeeman effect for the excited state, allowing for an unambiguous determination of g -tensors. Also, the polarization effects will be carefully investigated.

Erbium in SiO_x environment: ways to improve the $1.54\text{ }\mu\text{m}$ emission

G. Kocher^{a,*}, H. Przybylinska^{a,b}, M. Stepikhova^{a,c}, L. Palmetshofer^a, W. Jantsch^a

Abstract

The only way to obtain room temperature electroluminescence at $1.54\text{ }\mu\text{m}$ from Si diodes due to intra-atomic transitions of erbium is the excitation of $\text{SiO}_2\text{:Er}$ clusters by hot electron injected in a reverse biased diode. Impact excitation of erbium and thus electroluminescence can be achieved in tunnelling diodes, although at very small excitation volume, which would cover only a small fraction of a wave guide. Making use of an avalanche process allows one to increase the excitation volume considerably. This requires accurate control of doping gradients and thus knowledge of the electrical activity and the distribution of the implanted dopants. We present data from SIMS and Hall effect investigations, which demonstrate significant deviations from TRIM simulations of the implantation profiles and the hitherto assumed electrical activity of Er in such environment. We present optimum parameters for design and realisation of diodes working at room temperature. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Erbium luminescence; Electroluminescence; Precipitates

1. Introduction

The search for Si based light sources for integration into Si technology is considered to be of utmost importance in semiconductor physics. One of the most promising approaches to reach this goal is the integration of erbium ions into Si host crystals. These ions emit near infrared light at a wavelength of $1.54\text{ }\mu\text{m}$ resulting from a radiative transition within the 4f shell.

Depending on doping, annealing conditions and co-doping with light elements—especially with oxygen—erbium produces a big variety of centres in silicon. These centres can be distinguished by their characteristic luminescence line patterns [1]. For these centres with their well-defined geometry, intra-shell excitation of Er can be achieved in a forward biased p–n junction via an energy transfer from recombining electron–hole pairs.

These devices show a high internal quantum efficiency at low temperatures [2] but also strong thermal quenching of their luminescence above 150 K.

Two different mechanisms are assumed to be responsible for this quenching: an Auger effect [3] and energy back transfer of the Er excitation energy to the host via a defect level, which seems also to be participating in the transfer of energy from the host to the Er 4f shell [4]. This defect level is characteristic for oxygen co-doped Si:Er.

One way to reduce Auger quenching is excitation in a reverse biased p–n junction. Here, Er is excited by highly inelastic impact with hot electrons (“impact excitation”) injected to the Er-doped region in the breakdown regime. In this case, the thermal quenching of luminescence is negligible and room temperature luminescence can be achieved [5–7]. The cross-section for the impact excitation, however, is small and therefore the efficiency is rather low. Furthermore, it turned out that the emission spectra of reverse biased diodes are modified. It changes from the characteristic sharp line spectra caused by crystal field splitting with line widths of less than

*Corresponding author. Tel.: +43-732-2468-9649; fax: +43-732-2468-9696.

E-mail address: gudrun.kocher@jk.uni-linz.ac.at (G. Kocher).

1 nm to a less structured band with a width of approximately 20 nm.

These broad features originate from Er in SiO_x precipitates [8]. The incorporation of Er in SiO_x clusters is achieved by Er and O implantation and subsequent annealing above 950°C, the threshold temperature for appreciable oxygen migration and formation of SiO_2 precipitates [9].

Impact excitation of erbium and thus electroluminescence can be achieved in tunnelling diodes, although at a very small excitation volume. Electrons participating in the impact excitation need an energy of more than 0.8 eV. The small mean free path of these electrons restricts the excitation volume to a layer of less than 40 nm thickness surrounding the p–n junction [5–7]. Making use of an avalanche process allows one to increase the excitation volume considerably. This requires accurate control of doping gradients and thus knowledge of the electrical activity and the distribution of the implanted dopants.

We find from SIMS measurements, that at the high temperatures required for the precipitate formation in our devices, the implanted Er profile remains practically constant, but the distribution of the light dopants changes significantly. We also find that the as-implanted profiles deviate substantially from those obtained in TRIM code simulations [10]. Another change appears in the electrical activity of our “optical dopant”: Hall measurements show that the electrical activity is rather low under the preparation conditions used.

We discuss here the optimum parameters for design and realisation of diodes working at room temperature according to our findings.

2. Design considerations

An important property entering design considerations is, of course, the electrical activity of the Er centres. We investigated our SiO_x :Er precipitates by means of Hall effect measurements. The measurements were performed on samples prepared by implanting Er and O into high resistivity Si substrates (Fig. 1). Whereas for isolated

centres a large portion can be electrically active, for our sample, we found that the sheet concentration of the free carriers is only a few percent of that of the incorporated Er ions after annealing.

The easiest way to achieve EL from reverse biased p–n junctions is to produce diodes with large doping gradients that show tunnelling breakdown [5–7]. But, as mentioned above, the participating electrons with sufficient energy for this kind of excitation have only a short ballistic penetration range. Therefore, only a small fraction of the incorporated Er is excited and the total efficiency of such a device is rather low. Laser operation of such a device, for example, would be impossible because population inversion would be excluded already by geometrical constraints.

A diode working in the avalanche breakdown regime would extend the excitation volume 10 times (see Table 1). In order to get avalanche breakdown, the electric field strength has to be adjusted accordingly. This can be done by adjusting the doping gradient. To achieve avalanche conditions in Si at room temperature, the doping gradient must not exceed a value of 10^{23} cm^{-4} [11]. The doping gradient in implanted structures is usually obtained by applying TRIM code simulation. In order to gain information on the actual structure of our diodes, we applied SIMS for two different structures at various annealing temperatures (Fig. 2).

Fig. 1. Carrier concentration measured by Hall effect; substrate contribution was corrected by applying a two-sheet model.

Table 1
Parameters for tunnelling and avalanche diodes

	Tunnelling	Avalanche
Field strength, E (V/cm)	$> 10^6$	$< 6 \times 10^5$
Dopant gradient (lin. graded junct.) (cm^{-4})	$> 2 \times 10^{23}$	$< 10^{23}$
Voltage (V)	$< 4E_g/e$	$> 6E_g/e$
Er excitation cross-section (cm^2)	6×10^{-17} [7]	2.3×10^{-16} [12]
Excitation width (nm)	40	500

consideration has, thus, to be put into diode design in order to achieve avalanche rather than tunnelling breakdown in a diode. TRIM simulations turn out to be insufficient. After adjusting the diode design according to SIMS results, the intensity of the electroluminescence at room temperature increased by at least one order of magnitude.

Excitation of Si:Er with sub-band-gap energies

M.A.J. Klik*, T. Gregorkiewicz

Van der Waals–Zeeman Institute, University of Amsterdam, Valckenierstraat 65, NL-1018 XE, Amsterdam, The Netherlands

Abstract

We have performed photoluminescence excitation spectroscopy on molecular beam epitaxy grown Si:Er with a high-power near-infrared laser pulse. It was found that luminescence from the Er^{3+} ion, originating from the intra-4f-shell transition $^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$ could be induced by photon energies far below the band gap of the host material, but above energy of the 4f-shell transition. © 2001 Elsevier Science B.V. All rights reserved.

PACS: 32.80.Hd; 78.55.Ap

Keywords: Erbium; Silicon; Sub-band-gap excitation

The excitation mechanisms of rare-earth (RE) ions in semiconductors usually involve excitons or a RE-related energy level in the band gap of the host. The RE-ion can be photo-excited through the conduction band of the host material [1] or directly to the RE related level [2]. It is well known that the Er^{3+} ion can form a variety of complexes in the Si host material, most probably each with its own level within the band gap. Excitation spectroscopy is a powerful method to investigate these levels and their role in the excitation process. We have performed excitation experiments using a Nd:YAG (second harmonic) pumped optical parametric oscillator (OPO) crystal to produce a 5 ns pulsed laser beam with a wavelength range of 700–2200 nm and repetition rate of 20 Hz. The maximum pulse energy used in these experiments was 7 mJ at a wavelength of 700 nm. The sample under investigation was an oxygen-rich Si:Er layer of 1.8 μm , grown by molecular beam epitaxy (MBE) at a temperature of 560°C on top of a B-doped Si substrate. Luminescence from the sample was gathered using a single grating monochromator and a near-infrared photomultiplier tube with a flat response from 300 to 1600 nm. The sample was cooled to 10 K in an Oxford Instruments closed-cycle cryostat.

After excitation of the sample from the backside (substrate) with the OPO beam operating in the near infrared, a PL signal could be detected at 1.54 μm , originating from the intra-4f-shell transition $^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$ of the RE ion Er^{3+} . Fig. 1 shows the normalized photo-luminescence excitation (PLE) spectrum measured at 1539 nm at a temperature of 10 K (gray). The photon flux of the OPO-beam is indicated in black. It is clear from the picture that luminescence can be observed for excitation photon energies between the band-gap energy E_g of the host material and the

Fig. 1. PLE spectrum of Si:Er measured at a temperature of 10 K, using a high power pulsed excitation beam.

Fig. 2. Spectrum of Si:Er measured for four different excitation wavelengths. The PL intensity reduces for excitation energies close to that of the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transition in the 4f-shell of Er^{3+} .

energy of the intra-4f-shell transition. The cross section for excitation decreases monotonically with smaller photon energy and vanishes for an energy below this transition. No resonant features are present in the range 1125–2200 nm. Although multi-photon absorption seems an obvious explanation for the observed excitation spectrum, the dependence of PL intensity on OPO-beam power shows a completely linear behavior, indicating other processes to be responsible for the excitation of the RE-ion with sub-band-gap photon energies. Fig. 2 shows the spectra of the Er intra-4f-shell luminescence for excitation wavelengths from 1310 to 1460 nm. It can be seen that the luminescence intensity decreases when the excitation energy approaches the energy of the intra-4f-shell transition.

Fig. 3. PLE spectrum of GaAs:Er measured at 10 K.

At present, the observations cannot be explained by any of the (so far) considered models. For a better understanding of the processes responsible, more accurate measurements will be done on a variety of samples in the near future. For comparison, the PLE spectrum for MBE grown GaAs:Er was obtained using the same experimental setup (Fig. 3). Although both PLE spectra are very similar, the luminescence at 1.54 μm could only be observed for excitation wavelengths below 1000 nm.

Abstract

Formation processes of shallow donors in Czochralski-grown silicon coimplanted with rare-earth ions and oxygen are studied. There is no indication that rare-earth ions are components of the structures of shallow donors. However, intrinsic defects appear to be involved in the formation processes. These oxygen-related thermal donors survive even at $T = 900^\circ\text{C}$. They are responsible for the electrical conductivity in the implanted layers at cryogenic temperatures. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Rare-earth ions; Implantation; Thermal donors

1. Introduction

Earlier [1–3] it has been established that in Czochralski-grown silicon (Cz-Si) implanted with rare-earth (RE) dopants (Dy, Ho, Er and Yb) and annealed to $T = 700^\circ\text{C}$ three main kinds of donor centers make their appearance: shallow donors at $\approx E_C - 40\text{ meV}$ and deeper donor centers at $\approx E_C - (60-80)\text{ meV}$ and $\approx E_C - (110-140)\text{ meV}$; see Fig. 1. All of them were found to be oxygen-related, since their formation takes place only in the presence of oxygen, no matter in Cz-Si implanted with RE ions [1] or float-zone silicon (FZ-Si) coimplanted with RE ions and oxygen [3]. Without oxygen coimplantation in FZ-Si only one kind of dominating donors at $\approx E_C - 200\text{ meV}$ can be detected; see Fig. 1 and Ref. [3]. Besides, a comparative study of various dopants in Cz-Si allowed to conclude that the position of donor centers at $\approx E_C - (60-80)\text{ meV}$ and $\approx E_C - (110-140)\text{ meV}$ are dependent on the chemical nature of RE impurities [1]. This is why these

centers have been identified as (RE-oxygen)-related complexes [1–3].

In the present paper, most attention has been paid to the formation of oxygen-related shallow donors responsible for the electrical conductivity of implanted layers at cryogenic temperatures.

2. Experimental

The initial materials were p-type Cz-Si wafers of $\rho \approx 20\ \Omega\text{cm}$. The oxygen concentration varied over a wide range, from $\approx 2 \times 10^{17}$ to $\approx 1 \times 10^{18}\text{ cm}^{-3}$. In some cases, n-type Si:P epilayers of $\rho \approx 20\ \Omega\text{cm}$ were grown on low-resistivity p-type Cz-Si substrates and then implanted with Er ions.

RE ions, mostly Er, were implanted at energies of 1.0–1.2 MeV. The RE implantation dose Φ varied in the range of 5×10^{11} – $1 \times 10^{13}\text{ cm}^{-2}$. In the case of oxygen coimplantation, the energy of oxygen ions was between 0.11 and 0.18 MeV. The implanted samples were annealed at $T = 700^\circ\text{C}$ for 30 min in a chlorine containing ambient. The radiation damage is mostly recovered at this annealing stage. At implantation doses $\Phi(\text{RE}) \geq 5 \times 10^{11}\text{ cm}^{-2}$, the implanted layers of

Fig. 1. Donor centers determining the electrical conductivity of FZ-Si and Cz-Si implanted with RE ions and annealed at $T = 700^\circ\text{C}$. The donor levels are shown with respect to the conduction band of silicon.

about $0.5\ \mu\text{m}$ in thickness became n-type, even in the initially p-type Cz-Si samples.

Electrical measurements of the electron concentration in implanted layers versus temperature, $n(T)$, were taken by means of the Van der Pauw technique over the temperature range from $T \approx 20$ – $300\ \text{K}$. Analysis of $n(T)$ curves was carried out on the basis of the corresponding equations of charge balance [4,5]. Photoconductivity spectra of several implanted layers at cryogenic temperatures were recorded in the range of 200 – $800\ \text{cm}^{-1}$ with the aid of an IFS-113 V Bruker spectrometer. The resolution was $1\ \text{cm}^{-1}$.

In some cases, implanted samples were subjected to $0.9\ \text{MeV}$ electron irradiation at room temperature to produce A-centers (oxygen-vacancy complexes) for partial compensation of shallow donor states.

3. Results and discussion

By way of example, in Fig. 2, three $n(T)$ curves are shown for the FZ-Si epilayers coimplanted with Er and O ions. The Er dose was fixed at a maximum, $\Phi(\text{Er}) = 1 \times 10^{13}\ \text{cm}^{-2}$, whereas the dose of oxygen coimplant varied between $\Phi(\text{O}) = 5 \times 10^{13}$ and $5 \times 10^{14}\ \text{cm}^{-2}$.

Analysis of all the $n(T)$ curves revealed some interesting features of the donor formation processes in Er implanted layers.

First, at $\Phi(\text{Er}) \leq 5 \times 10^{12}\ \text{cm}^{-2}$ the concentration of shallow thermal donors in Cz-Si:Er with high oxygen concentrations (about $1 \times 10^{18}\ \text{cm}^{-3}$) varies directly with the Er implantation dose. This observation is consistent with our earlier conclusion [3] that the intrinsic defects produced by Er ions play a key role as nucleation sites of oxygen aggregates (shallow thermal donors). In this way, the shallow thermal donors are substantially stabilized as compared to those usually formed during oxygen precipitation processes in conventional Cz-Si at

Fig. 2. Electron concentration against reverse temperature in the Fz-Si coimplanted with Er and O ions and annealed at $T = 700^\circ\text{C}$. Dose $\Phi(\text{Er}) = 1 \times 10^{13}\ \text{cm}^{-2}$. Dose $\Phi(\text{O}) = 5 \times 10^{13}\ \text{cm}^{-2}$ (open circles), 1×10^{14} (solid circles) and $5 \times 10^{14}\ \text{cm}^{-2}$ (solid triangles). Concentration of shallow donors (open circles), $2.8 \times 10^{16}\ \text{cm}^{-3}$.

$T = 700^\circ\text{C}$: cf. also [6–8]. The shallow thermal donors in Cz-Si:RE survive even after annealing to $T = 900^\circ\text{C}$ [1,2]. At $\Phi(\text{Er}) > 5 \times 10^{12}\ \text{cm}^{-2}$ there is a pronounced trend towards saturation of the concentration of shallow donors in Cz-Si:Er.

Second, as would be expected, the damage produced by oxygen ions turned out to be not so important for the formation of shallow thermal donors. Actually, the total concentration of shallow donors is close to $3 \times 10^{16}\ \text{cm}^{-3}$ at $\Phi(\text{O}) = 5 \times 10^{13}$ and $1 \times 10^{14}\ \text{cm}^{-2}$, whereas at $\Phi(\text{O}) = 5 \times 10^{14}\ \text{cm}^{-2}$ it even drops by 20%; see also Fig. 3. This

slight decrease may be due to increasing formation rate of electrically inactive oxygen precipitates in oxygen-rich samples.

In contrast to little importance of oxygen ions as a damaging factor, the contribution of heavy Er ions to the production of intrinsic defects being involved in the formation of shallow donor centers can be characterized in a quantitative way. Really, analysis of the curves $n(T)$ shown in Figs. 2 and 3 points to the fact that the production of oxygen-related shallow thermal donors in FZ-Si:Er:O versus FZ-Si:O is enhanced by three times. This observation agrees well with the conclusion concerning the involvement of intrinsic defects in the oxygen agglomeration processes. As seen from Fig. 3, only one kind of shallow thermal donors, similar to those formed in FZ-Si:Er:O, is also produced in FZ-Si:O, thus demonstrating the involvement of Er ions in the formation of deeper donor centers at $\approx E_C - 70$ and 120 meV.

Third, the shallow thermal donors considered, like similar donor species formed during heat treatment of conventional Cz-Si at $T < 700^\circ\text{C}$ [6], are distributed over their ionization energies from ≈ 40 to ≈ 25 meV, the gravity center being placed at ≈ 40 meV. This is evident from the analysis of the low-temperature portions of $n(T)$ curves whose slopes change over the interval given above with increasing Er dose. It is possible to prove this model in another way by partial compensation of the shallow donors due to deep acceptors, e.g. vacancy-oxygen complexes (so-called A-centers at $\approx E_C -$

170 meV [9]) produced in Cz-Si:Er layers subjected to fast-electron irradiation. A compensation effect of shallow thermal donors due to A-centers in electron irradiated Cz-Si:Er:O is shown in Fig. 4. What is more, the quantitative analysis showed that the distribution of these donors as well as the concentrations of Er-related deep donor centers do not change noticeably after irradiation, so the whole $n(T)$ curves for electron irradiated layers can be described in a satisfactory way by changing the concentration of A-centers only; see Fig. 4.

Fourth, our photoconductivity measurements on Dy-implanted layers revealed the presence of Thermal Double Donors (TDDs); see Fig. 5. Their concentration is roughly estimated to be about 10^{15} cm^{-3} . This family of thermal donor states at $\approx E_C - 70$ and $\approx E_C - 140$ meV usually makes its appearance in conventional Cz-Si during heat treatment at $T \leq 500^\circ\text{C}$; see for instance review paper [10]. They are known to be unstable above $T = 600^\circ\text{C}$. After annealing of the Dy implanted layers to $T = 700^\circ\text{C}$ one could expect to detect the presence of TDDs in trace concentrations only, about 10^{13} cm^{-3} .

4. Conclusions

The information gained in the present work provides additional strong support for our earlier identification of oxygen-related shallow thermal donors in Si implanted

Fig. 3. Fragments of the $n(T)$ curves shown in the Fig. 2. For comparison purposes, the electron concentration against reverse temperature in the same FZ-Si implanted solely with O ions at $\Phi(\text{O}) = 5 \times 10^{14}\text{ cm}^{-2}$ and annealed at $T = 700^\circ\text{C}$ is also given (open diamonds). Concentration of [ErO]-I centers (open circles), $2.5 \times 10^{16}\text{ cm}^{-3}$. Concentration of [ErO]-2 centers (open circles), $1.0 \times 10^{17}\text{ cm}^{-3}$.

Fig. 4. Electron concentration against reverse temperature in the Cz-Si:Er before (open circles) and after fast electron irradiation (solid circles). Dose $\Phi(\text{Er}) = 1 \times 10^{13}\text{ cm}^{-2}$. Post-implantation annealing was performed at $T = 700^\circ\text{C}$. After the implantation and annealing the Er-doped layer was irradiated with 0.9 MeV electrons at a dose $1 \times 10^{17}\text{ cm}^{-2}$.

Fig. 5. Photoconductivity spectrum in the Cz-Si:Dy. Dose $\Phi(\text{Dy}) = 1 \times 10^{13} \text{ cm}^{-2}$. Postimplantation annealing was performed at $T = 700^\circ\text{C}$. The spectrum was recorded at $T \approx 30 \text{ K}$ under bandgap illumination. Three species of Thermal Double Donors are identified.

with RE impurities, first of all erbium. These shallow thermal donors are responsible for the electrical conductivity in implanted layers at cryogenic temperatures. The contribution of intrinsic defects produced by heavy RE ions to the formation of shallow donor centers has been studied in detail. The intrinsic defects serve as nucleation sites of growing oxygen aggregates.

Abstract

Photoluminescence excitation spectroscopy is used to study the location of Er^{3+} ions in oxygen-rich silicon and its excitation mechanisms. We find that Er luminescence excited within the range of the $^4\text{I}_{13/2}$ excited manifold of Er^{3+} consists of two features: a broad band independent of excitation wavelength, λ_{exc} , and a fluorescence narrowed line, dependent on λ_{exc} . These results show that Er^{3+} ions are excited via two energy transfer channels: the first one is due to non-radiative transfer of energy from excitons to the $^4\text{I}_{13/2}$ state, whereas the second one, leading to line narrowing, is typically resonant, site selective excitation of Er ions in silica glass. The results show that excitable Er ions are located most probably within nano-precipitates of SiO_2 . © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Erbium-doped silicon is a promising material for light emitters operating at 1.54 μm , the most important wavelength for optical communication and prospective Si-based optoelectronics [1]. In spite of many efforts, however, the efficiency of the 1.54 μm luminescence of Er^{3+} at room temperature (RT) is still too low for practical applications. The main reason for this appears to be an indirect excitation mechanism for the 4f shell of Er^{3+} , dominated by Auger-type interaction with charge carriers and excitons [2]. On the one hand, charge carrier mediated mechanisms of excitation ensure efficient energy transfer to Er centres at low temperatures. On the other they are also responsible for thermal quenching of the luminescence.

The quenching can be substantially reduced by codoping with oxygen [3] and also by employing wide band gap semiconductor hosts [4]. Efficient photoluminescence (PL) of Er^{3+} was obtained at RT in disordered Si-based materials with high oxygen contents, such as

porous silicon [5], semi-insulating polycrystalline silicon [6,7], or oxygen-rich silicon grown by laser ablation [8]. Moreover, the only Si:Er-based light emitters operating at RT were shown to employ silica nano-precipitates containing the Er [9,10].

The weak temperature quenching of the PL of Er^{3+} and lack of sharp emission lines, typical of oxygen-lean crystalline Si:Er [11], suggest that all the Er ions in oxygen-rich silicon layers are located within silica nano-precipitates. For such a location, direct optical excitation of Er^{3+} via absorption of photons should, in principle, be possible. It would result in fluorescence line narrowing (FLN), as different Er sites in silicon oxide precipitates would be selectively pumped [12].

In general, we should not expect direct optical excitation to be observed for pump wavelengths in the visible, because of the much higher absorption cross section of amorphous silicon (a-Si) than that of Er and, in effect, a dominant exciton mediated transfer of energy to the Er. On the other hand, resonant excitation of Er^{3+} ions should be easier to observe near 1 μm , where absorption in a-Si is relatively small.

In this work, we show using PLE spectroscopy and selectively excited PL that those Er^{3+} ions that can be

*Corresponding author. Tel.: +48-22-843-68-61; fax: +48-22-843-09-26.

E-mail address: kozana@ifpan.edu.pl (A. Kozanecki).

excited optically in Si(O):Er are indeed located within precipitates of SiO_x (or SiO₂) phase.

2. Experimental

The composition of the investigated layers was approximately SiO_x with an Er concentration of $\sim 10^{20} \text{ cm}^{-3}$. PL and PLE measurements were performed at helium temperatures. PL was excited using a Ti:sapphire laser chopped at 18 Hz and detected with liquid nitrogen cooled Ge detector. The spectra were normalised to a constant excitation power. A quartz sample implanted with 800 keV Er ions and annealed at 800°C served us as a reference.

3. Results and discussion

PLE spectra, measured at 5 K, of Er³⁺ in our samples of SiO:Er are presented in Fig. 1 for different detection wavelengths, λ_{det} . For an excitation wavelengths, λ_{exc} , within the range of ~ 975 – 986 nm the spectra depend on λ_{det} and for larger λ_{det} , the peak positions shift towards longer wavelengths. On an energy scale, the shift follows exactly a 1:1 correspondence. For λ_{exc} beyond the 975–986 nm range the PLE spectra are flat and do not depend on λ_{det} .

Fig. 2 shows selectively excited PL spectra of Er³⁺ near 1.5 μm . The spectra depend in a characteristic way on the pump energy. For $975 < \lambda_{\text{exc}} < 986$ nm in each spectrum, a narrow PL can be distinguished whose spectral position shifts reflecting the changes of the pump wavelength. This narrow PL is superimposed on a broad band which does not change in shape with λ_{exc} . For excitation at $\lambda_{\text{exc}} < 975$ nm and > 990 nm only a

broad emission is observed. Its intensity depends slightly on the pump wavelength.

For comparison, the PLE spectra in quartz implanted with Er ions at 800 keV and annealed at 800°C were measured (Fig. 3). Similarly as in Fig. 1, the peak positions in the spectra follow the changes in the detection energy. However, in contrast to Si(O):Er, a long wavelength cut-off, which for increasing λ_{det} shifts to shorter wavelengths, is clearly seen. The Er emission cannot be excited with pump wavelengths longer than 986 nm. As a result, it can be assumed that the low energy edge of the $^4I_{11/2}$ state is at ~ 1.2575 eV.

In quartz, excitation of the Er³⁺ is achieved by optical pumping—each laser wavelength can selectively excite some Er centres having an energy of the $^4I_{11/2}$ state at

Fig. 2. Site-selective PL spectra of Er³⁺ in laser ablated silicon.

Fig. 3. PLE spectra of Er³⁺ ions in quartz implanted and annealed at 800°C.

Fig. 1. PLE spectra of Er³⁺ in laser ablated silicon at 7 K.

resonance with the laser [12]. Then multi-phonon relaxation to the $^4I_{13/2}$ state of the originally excited ion takes place followed by emission near 1.5 μm . Since at low temperatures phonon-absorption-assisted excitation of Er ions is not possible, the centres having energies of their $^4I_{11/2}$ state higher than the pump light energy, by principle, cannot be excited. Therefore, a long-wavelength cut-off dependent on the λ_{det} is observed in the PLE spectra (Fig. 3).

The PLE spectra and selectively excited luminescence of erbium show that two excitation mechanisms of Er^{3+} are active. The first one is responsible for the dependence of the PL on λ_{exc} and λ_{det} . This is typical of site-selective excitation of Er ions in glasses and quartz [12,13]. The similarities in the PLE spectra in Figs. 1 and 3 indicate that the local atomic environment around Er ions in quartz and in Si(O):Er are similar. This finding supports our earlier suggestion that Er ions in Si(O):Er are located inside oxygen-rich clusters, presumably within micro- or nano-precipitates of SiO_x . Taking into account the composition of the layers ($\text{Si:O} \sim 1:1$) and the absence of sharp lines typical for the luminescence of Er^{3+} in crystalline Si at low temperatures [11], this conclusion appears to be justified. A larger inhomogeneous broadening of the PL bands in the oxygen-rich silicon implies a much larger variety of Er centres as compared to quartz. Such a location explains also the low temperature quenching of the Er PL [10].

The second excitation process is responsible for the constant background in the PLE spectra (Fig. 1) and the broad emission observed for selectively excited PL (Fig. 2). It can be attributed to the excitation via the band edge of silicon. As excitons are formed in a silicon rich phase or in Si micro-precipitates, which have a band gap E_g equal to that of bulk Si, only an excitation to the $^4I_{13/2}$ of Er^{3+} state is possible due to non-radiative energy transfer from excitons. The efficiency of such a process practically does not depend on the excitation wavelength in this relatively narrow range of 960–1000 nm, since the absorption cross-section of a-Si is almost constant there.

4. Summary

The results of PLE and selectively excited PL measurements prove that Er ions in oxygen-rich silicon are located inside silicon oxide clusters as they reveal, at

least in part, the behaviour typical of rare earth dopants in glasses. We also show that for such a location two excitation mechanisms of Er ions are possible: (i) resonant optical excitation to the $^4I_{11/2}$ state, which is responsible for fluorescence line narrowing, and (ii) excitation via the band edge of silicon to the $^4I_{13/2}$ state. The latter process is responsible for broad luminescence in selectively excited PL and a constant background in the PLE spectra.

Erbium excitation across the bulk of silicon wafer: an effect of p–n junction at Si/Si:Er interface

N.Q. Vinh^{a,*}, I.N. Yassievich^b, T. Gregorkiewicz^a

^a Van der Waals—Zeeman Institute, University of Amsterdam, 65 Valckenierstraat, NL-1018 XE Amsterdam, Netherlands

Abstract

It is known that emission from Er ions implanted into a silicon wafer can be excited by illumination of the non-implanted side of the sample. In such a configuration, energy has to be transferred across the entire thickness of the sample (300–500 μm), which exceeds by two orders of magnitude absorption depth of a 514.5 nm line of an Ar ion laser. We have shown that for the non-implanted side illumination configuration, the energy transfer process leads to a delay in the onset of Er photoluminescence signal, whose magnitude depends on the excitation power. In the present contribution, we investigate the microscopic mechanism responsible for this delay. We postulate that it can be related to exciton dissociation at a p–n junction created by Er doping at a Si/Si:Er interface. We confirm this hypothesis by showing that the actual value of the delay time can be tuned by a bias voltage applied to the junction. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Erbium doping of silicon has recently become an extensively studied subject. The rare-earth erbium, when incorporated in silicon in the trivalent charge state, shows characteristic luminescence from an intra-4f transition at a wavelength of 1.54 μm . This emission can be observed both under optical or electrical excitation. This optical doping technique seems to be a promising way around the problem of the indirect band gap of silicon. If sufficiently high Er concentrations could be incorporated and activated, it would become possible to fabricate light emitting diodes, lasers, or optical amplifiers, based on silicon. This would enable the integration of optical and electronic technologies on the same chip. Therefore, a thorough understanding of the microscopic process responsible for the energy

transfer between the crystalline silicon matrix and the 4f-electron core of Er ions is of prime importance.

Some time ago it was reported that Er PL can be generated from the Er-implanted crystalline silicon wafer under conditions when the laser beam operating in the visible region is pointed at the non-implanted side of a wafer [1]. In such a configuration, excitation is absorbed at a distance of 350–500 μm from the Er-doped layer. Careful investigation [2] showed that PL spectra obtained under implanted and non-implanted side excitation were identical in their structure. Therefore, the same optically active centers are excited in both experimental configuration, i.e., excitation diffusion across the bulk of the material does not influence the “final” excitation mechanism responsible for the energy transfer to the rare-earth ion core. From the measurements of the kinetics of the process, it has been found out that for the non-implanted side excitation, the Er-related PL signal appears with a considerable delay of the order of a few milliseconds with respect to the excitation pulse. The actual magnitude of this delay was

*Corresponding author. Tel.: +31-20-525-5644; fax: +31-20-525-5788.

E-mail address: nguyen@science.uva.nl (N.Q. Vinh).

found to depend on the laser power. While the appearance of Er-related PL upon the backside illumination is normally attributed to long-range exciton diffusion, the observed long delay time was inconsistent with that model. Taking into account the appropriate material parameters, i.e., exciton life time and diffusion constant, a delay of a few microseconds can be expected, clearly at variance with the experiment.

In the current contribution, we explore the exciton dissociation at a p–n junction at Si/Si:Er interface as a possible mechanism responsible for the observed delay. We report that the actual value of the delay time can be changed by bias voltage applied to the junction.

2. Experimental

The experimental configuration used in this study is illustrated in Fig. 1. It allowed for an easy change between excitation of either the implanted side or the backside of the sample, while a DC voltage (–10 to +10 V) could be applied by electrical contacts on both surfaces. In both excitation modes, PL was collected from the Er-implanted side. The experiments were performed in a closed cycle cryostat in the temperature range between $T \approx 15$ and 150 K. An on–off modulated (25 Hz) argon laser operating at $\lambda = 514.5$ nm was used as an excitation source. The emerging PL signal was monitored with a high-sensitivity germanium detector (Edinburgh Instruments).

The investigation was conducted for a low-energy (300 keV, 3×10^{12} cm $^{-2}$ dose) Er-implanted oxygen-rich p-type (B-doped) Cz–Si wafer of approximately 350 μ m thickness. The sample was also co-implanted with oxygen (40 keV, 3×10^{13} cm $^{-2}$ dose) and annealed at 900°C in a nitrogen atmosphere for 30 min.

Fig. 1. Experiment allowing for excitation either of surface of the sample or electrical bias. Photoluminescence is detected from the Er-implanted side of the sample.

3. Results and discussion

For the sample used in the investigations, a strong PL spectrum was observed under different excitation conditions. Fig. 2 compares PL spectra obtained with and without electrical bias. As can be seen, spectral structure is not influenced by the bias and conclude that the same Er-related optical centers are activated under conditions of different electrical bias, as used in the present study.

We will first consider the case of excitation by a green laser pointed at the wafer side opposite to the Er-implanted layer. In this case, the relevant parameters are as follows: photon energy $h\nu = 2.4$ eV, absorption coefficient $\alpha = 10^4$ cm $^{-1}$, and pumping intensity $I = 3 \times 10^{16}$ cm $^{-2}$ s $^{-1}$. To analyze the exciton diffusion at distance s , we should solve the diffusion equation with a source of excitons near the surface ($x = 0$)

$$\frac{\partial N_{\text{ex}}}{\partial t} = D \frac{\partial^2 N_{\text{ex}}}{\partial x^2} - \frac{N_{\text{ex}}}{\tau_{\text{ex}}} + \alpha I g(t) \exp(-\alpha x) \quad (1)$$

for a continuous pumping

$$\frac{\partial N_{\text{ex}}}{\partial x} = 0 \quad \text{at } x = 0. \quad (2)$$

From this, we can get the exciton density flux $j_{\text{ex}}(x, t) = -D \partial N_{\text{ex}} / \partial x$ at $x = s \gg x^{-1}$ [3,4]:

$$j_{\text{ex}}(s, t) = \frac{I}{\sqrt{\pi}} \int_0^{t/\Delta t} dz \frac{1}{z^{3/2}} \exp\left[-\left(\frac{1}{z} + \frac{s^2}{4L^2} z\right)\right]. \quad (3)$$

Here N_{ex} , D , and τ_{ex} are the exciton concentration, diffusion coefficient, and the exciton lifetime, respectively. We introduce parameter $\Delta t = s^2/4D$ and the diffusion length of the excitons $L = \sqrt{D\tau_{\text{ex}}}$. The parameter Δt determines the diffusion-related time delay, i.e., the time necessary for an exciton to arrive at distance s due to diffusion. For a reasonable parameter value of $D = 90$ cm 2 s $^{-1}$ [5], the time delay $\Delta t = s^2/4D$ due to diffusion for the distance of

Fig. 2. PL spectra obtained for non-implanted side excitation with and without electrical bias.

$s \approx 350 \mu\text{m}$ is about $3.5 \mu\text{s}$, which is two order of magnitude faster than observed in the experiment.

Having excluded exciton diffusion across the silicon wafer as a possible reason for the long delay time observed in appearance of PL signal, we will now consider charge accumulation at Si/Si:Er interface as an alternative mechanism. Indeed, it is generally accepted [6] that erbium implantation into oxygen-rich silicon leads to the formation of donor centers with ionization energies in the $0.1\text{--}0.25 \text{ eV}$ range and concentration comparable to that of Er ions. Since the sample under investigation was prepared from p-type Si ($[B] = 10^{15} \text{ cm}^{-3}$) and the Er concentration in the implanted layer is $\sim 10^{18} \text{ cm}^{-3}$, a p–n junction should occur in equilibrium at the boundary with the Er-implanted layer. The excitons arriving at the p–n junction will therefore experience the electric field related to the depletion layer formation. In this field, whose value can reach 10^4 V/cm , the exciton will be divided into electrons and holes. These will gradually accumulate at a junction lowering the potential. Excitons will start to appear in the Er-doped layer and excite Er only after the depletion region has been removed due to charge compensation. We can expect that this effect can be influenced by biasing the junction. As illustrated in Fig. 3, the actual delay time can indeed be reduced under the forward bias condition, the effect being very similar to the earlier reported delay reduction upon increase of excitation density [2]. Fig. 4 shows in detail how the experimentally measured delay time can be turned by the electrical bias applied to the junction. For the purpose of this experiment, contacts were made with silver paste on the opposing faces of the sample, which was then placed in the low-temperature experimental set-up allowing for measurements in the two illumination configurations. In addition, DC voltage from a stabilized power supply could now be applied,

providing electric field across the thickness of the sample. Prior to the PL experiment, we measured the low-temperature I – V characteristics of the sample. The result, also depicted in Fig. 4, confirms that Er implantation into a p-type silicon substrate results in p–n junction formation. We then proceeded to investigate the PL signal delay time in the backside illumination configuration and under the applied bias. While the Er-related PL spectrum did not change (see Fig. 2), the kinetics of the signal were clearly influenced by the bias. As can be seen, under conditions of reverse bias the delay time can be increased as the depletion region increases; the delay time can be brought down to zero under forward bias. Following our interpretation, the applied forward bias reduces the depletion region to a level at which excitons diffusing towards the Er-implanted layer are no longer destroyed.

In order to evaluate quantitatively if the junction effect can account for the observed delay, we have to estimate the time necessary to compensate the change in the depleted region. The width of the depletion region is controlled by boron doping, and at low temperatures is given by

$$W \approx \sqrt{\frac{\varepsilon(E_g - (E_D + E_B)/2)}{2\pi e^2 N_B}}, \quad (4)$$

where E_g is the energy gap, E_D and E_B are the binding energies of the Er-related donors and boron acceptors, respectively, e is the electron charge, and ε is the dielectric constant of silicon. The calculated depletion region of about $1 \mu\text{m}$ is situated predominantly in the p-type layer. The negative charge ($-N_B W$) is accumulated in the depletion region of the p-type layer, and the same positive charge ($+N_D W_D = N_B W$) is in the n-type layer.

Fig. 3. Time development of the Er-related PL signal under non-implanted side excitation with electrical bias. The laser pulse is also shown.

Fig. 4. Delay time of the Er PL observed for non-implanted side excitation as a function of electrical bias, and I – V characteristics of the (p-type) sample used in the experiment.

The time δt which is needed for the destruction of the p–n junction can be found from the equation

$$\int_0^{\delta t} dt j_{\text{ex}}(s, t) = N_B W, \quad (5)$$

where $j_{\text{ex}}(s, t)$ is given by Eq. (3). Assuming the fast diffusion process, we can use the equilibrium formula for finding the delay time δt

$$\delta t \frac{\sqrt{\pi}}{2\sqrt{2}} I \exp(-s/L) = N_B W. \quad (6)$$

From here the diffusion length L can be estimated. With the experimentally obtained value of the delay time δt in the millisecond range, we get $L \approx 60 \mu\text{m}$. Such a diffusion length corresponds to an exciton lifetime of $\tau_{\text{ex}} \approx 0.4 \mu\text{s}$. In our experiment, the lifetime of the free excitons is controlled by capture at neutral boron acceptors. This assumption is supported by the observation of bound exciton luminescence for non-implanted side excitation. In this case, we have

$$\frac{1}{\tau_{\text{ex}}} = N_B \sigma_{\text{ex}} \langle v \rangle, \quad (7)$$

where $\langle v \rangle$ and σ_{ex} are the thermal velocity and capture cross-section of free excitons, respectively. The calculated exciton lifetime corresponds to $\sigma_{\text{ex}} \approx 1.2 \times 10^{-15} \text{ cm}^2$, which is a reasonable value. Therefore, we conclude that the presence of the p–n junction can lead to the observed delay time.

4. Conclusions

The characteristic $\lambda = 1.54 \mu\text{m}$ emission of Er^{3+} ions implanted into a silicon wafer is excited by an Ar laser

pointed at the non-implanted side of the sample. In this experimental configuration, energy is transferred across the bulk of a Si wafer before reaching the Er-doped layer. It is found that the exciton diffusion across a p–n junction created by Er doping at the Si/Si : Er interface leads to a considerable delay between the excitation pulse and the appearance of Er-related PL. This is caused by the time necessary to accumulate charge to compensate the voltage at the junction and prevent dissociation of arriving excitons. It is shown that the particular value of this delay time can be changed by application of electric bias to the junction. Results of the research confirm that excitons are responsible for Er excitation in crystalline silicon at cryogenic temperatures.

Abstract

The electrically active centers in light-emitting Si:Er/Si structures grown by an original sublimation MBE (SMBE) method are investigated using admittance spectroscopy and deep level transient spectroscopy. It is shown that free carrier concentration in investigated structures is determined by shallow donors with ionization energies varying from 0.016 to 0.045 eV. The essential difference between deep level defects observed in SMBE Si:Er/Si structures and in Si:Er/Si structures produced by ion implantation is revealed. The causes of observed distinctions between electrical and optical properties of SMBE structures as well as distinctions between SMBE and ion implanted Si:Er/Si structures are discussed. © 2001 Elsevier Science B.V. Keywords: Sublimation MBE; Si:Er/Si structures; Electrically active centers

1. Introduction

Silicon doped with erbium has been attracting attention as promising material for producing effective light emitters radiating in the range of the maximal transparency of silica glass optical fibers ($\lambda \approx 1.5 \mu\text{m}$). Recently, there were demonstrated Si:Er/Si structures with rather high photo- (PL) and electroluminescence (EL) including PL and EL at room temperature produced with an original sublimation MBE method (SMBE)—MBE variant, in which molecular flows of Si and Er are formed using sublimation of Si crystal initially doped with Er and other necessary dopants [1–4].

We report here on electrically active centers detected in light-emitting SMBE Si:Er/Si structures and their transformation caused by post-growth heat treatment. The observed distinctions between electrical and optical

properties of SMBE structures as well as distinctions between SMBE and ion implanted Si:Er/Si structures are discussed.

2. Experimental

We investigated uniformly doped Si:Er/Si structures grown on n-Si and p-Si substrates with (100) orientation and specific resistivity of 20, 10 and $0.005 \Omega\text{cm}$. The sublimating sources were plates cut from Si:Er ingots with Er and O contents up to 5×10^{20} and $1 \times 10^{19} \text{cm}^{-3}$, respectively. The growth temperature varied from 400 K up to 600 K and the thickness of the layers from $0.2 \mu\text{m}$ up to $3 \mu\text{m}$. The post-growth annealing of the structures was carried out at $T = 900 \text{ K}$ in H_2 atmosphere.

Energy levels in the band gap of Si were investigated using DLTS and admittance spectroscopy at the temperature range from 10 to 350 K. Admittance measurements were conducted in a frequency range

*Corresponding author. Tel.: +7-831-267-5037; fax: +7-831-267-5553.

from 100 Hz to 1 MHz. The conductance and capacitance components of the current passing through the sample under investigation were taken by synchronous detection of the signal. DLTS measurements were performed at 400 kHz using double boxcar integrating technique [5]. Combining DLTS and admittance measurements has allowed us to identify both shallow and deep levels.

Schottky contacts were prepared by thermal evaporation of Pd onto the sample surface at 6×10^{-6} torr. The ohmic contact was prepared by rubbing an In–Ga alloy onto the back surface of the sample or evaporating a Schottky contact of large size (Si:Er layers on high-resistance p-Si substrates).

3. Results and discussion

All investigated SMBE Si:Er layers were n-type, irrespective of the growth temperature and annealing conditions. The free carrier concentration as it was shown by admittance measurements was 10^{16} – 10^{18} cm $^{-3}$ at $T = 300$ K and was determined by shallow centers with ionization energies of 0.016–0.045 eV. The background contamination introduced by the apparatus during SMBE process was near 2×10^{13} cm $^{-3}$ [4,6]. Note that this estimation does not take into account the residual impurities containing in Si:Er sources.

The admittance spectra $C(T)$ and $G(T)$ shown in Fig. 1 are taken at zero bias and test signal frequency of 80.6 kHz. Note that the peak in $G(T)$ and the step in $C(T)$ are caused by freezing out of the carriers in the neutral region of Schottky diode and the corresponding enhancement of its resistance which is inserted in turn with the capacitance of the space charge region. The change of test frequency results in a shift of the observed admittance spectra along the temperature axis. At the bottom of Fig. 1 an Arrhenius plot is given. The ionization energy obtained from the slope of the Arrhenius plot has the value of 0.016 eV. During data processing, we have considered the temperature dependence of the effective density of states in the conduction band $N_c(T) \sim T^{3/2}$ neglecting the temperature dependence of the carrier mobility.

The type of conductivity fixed by these shallow centers and their forming conditions encourage to relate them to thermal donors—oxygen-defect complexes formed in Si crystals under heat treatment. The role of Er in forming these centers is not clear up to now. Probably, the Er atoms because of their greater size in comparison with Si atoms introduce appreciable distortions to the Si lattice and accelerate thermal donor formation [7]. There are distinctions between the ionization energies of shallow levels observed in SMBE layers grown from various Si:Er sources. Probably, they are caused by distinctions in impurity contents of different Si:Er sources, espe-

Fig. 1. Admittance spectra of shallow impurities in SMBE Si:Er/Si structure. The spectra are taken at frequency $f = 8 \times 10^2$ to 8×10^4 Hz and $U_{\text{bias}} = 0$.

cially it concerns such impurities as C, N, O which may be involved in the observed shallow defects.

A deep defect concentration is rather low in investigated SMBE structures. As-grown layers show usually a relative trap density $N_T/(N_D - N_A) < 0.1$. The ionization energies are in the range of 0.15–0.45 eV (Fig. 2). Their concentrations do not depend on the type of the used substrate and depend strongly on the growth and annealing conditions. Trap concentrations are maximal in layers grown at lower temperature ($T_{\text{growth}} < 500$ K) and decrease with increase of T_{growth} . The distinctive feature of these defects is that they are completely annealed by an additional post-growth heat treatment in particular by an annealing at 900 K during 30 min in H_2 atmosphere. In contrast, the post-growth annealing at the same conditions causes the transformation of light emitting centers but does not destroy the PL as a whole (Fig. 3). The PL connected with Er^{3+} passes through the minimum at $T_{\text{annealing}} = 750$ K and then strongly increases up to $T_{\text{annealing}} = 900$ K. It concludes that above mentioned deep electrically active centers do not participate in the energy transfer to Er^{3+} ions. Most likely, they are related to growth defects.

This is the most essential difference between the electrically active centers observed in SMBE and implanted Si:Er/Si layers. In implanted layers, one detects deep levels in the range of 0.1–0.3 eV including

Fig. 2. DLTS spectra of a SMBE Si:Er/Si structure as-grown and after annealing ($T_{\text{growth}} = 430$ K, annealing conditions: 900°C , 30 min., H_2). The DLTS spectra are taken at $\tau_{\text{window}} = 0.6$ ms, $U_{\text{bias}} = -2$ V. 1—calibration pulses, the amplitude of calibration pulse is $\Delta C = 10^{-3} \times C$, where C is the diode capacitance at the temperature of calibration.

the level $E_c - 0.15$ eV which according to nowadays concepts is responsible for the transfer of energy to Er^{3+} [8]. In SMBE layers despite of the intensive PL connected with erbium we could not detect deep levels in the same energy range. We have summarized below some results obtained from capacitance and PL experiments with the Si:Er/Si structure uniformly doped with Er in SMBE process and revealing the intensive PL at liquid helium temperature. Its parameters are as follows: the substrate is Si:B, $20 \Omega\text{cm}$; T_{growth} is 500°C ; the Si:Er layer width is $\sim 2.7 \mu\text{m}$; the structure was annealed at 800°C (30 min, H_2). Free carrier concentration slightly increases from 3×10^{16} on the surface to $2 \times 10^{17} \text{cm}^{-3}$ in the interior of the Si:Er layer; Er and O concentrations determined from SIMS measurements are 1×10^{18} and $3 \times 10^{19} \text{cm}^{-3}$ accordingly. The concentration of optically active centers related to erbium $N_{\text{Er}}^{\text{opt}}$ estimated from PL measurements is $2 \times 10^{16} \text{cm}^{-3}$ [9]. On the other hand, the concentration of electrically active centers with the ionization energy in the range of 0.1–0.3 eV that could participate in the transfer of energy to Er^{3+} ions (via the mechanism of an exciton capture [8]) $N_{\text{Er}}^{\text{el}} < 1 \times 10^{13} \text{cm}^{-3}$ (DLTS data). So, huge distinction between $N_{\text{Er}}^{\text{opt}}$ and $N_{\text{Er}}^{\text{el}}$ revealed in this experiment indicates that most probably the additional channels of energy transfer to Er^{3+} ions take place in

Fig. 3. PL spectra of uniformly doped Si:Er/Si structure depending on $T_{\text{annealing}}$. $T_{\text{growth}} = 430$ K [3].

SMBE Si:Er/Si structures in comparison with ion implanted ones.

4. Conclusions

In this contribution, we have presented the investigation of electrically active centers in Si:Er/Si structures produced by an original SMBE method. We have shown that the free carrier concentration is determined by shallow donors with ionization energy of 0.016–0.045 eV. The most unexpected result is that we have not yet detected any electrically active centers responsible for the energy transfer to Er^{3+} ions in investigated SMBE structures. So, we assume the presence of complementary channels in SMBE structures for the energy transfer to Er^{3+} ions in comparison with ion implanted structures.

Abstract

We present the findings of high efficient Er^{3+} -related $^4\text{I}_{13/2} \leftrightarrow ^4\text{I}_{15/2}$ absorption and emission from self-assembled quantum wells (SQW) embedded in silicon microcavities. The microcavities of this art are prepared by the short-time diffusion of boron into the Si(100) wafer doped with erbium. The intraband electron transitions accompanied by tunneling through strongly coupled SQW series are observed to excite the $^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$ Er^{3+} -intracentre emission that is enhanced in the range of the Rabi splitting revealed by the transmission spectra. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Self-assembled silicon quantum wells; Erbium-related centres; Luminescence

1. Introduction

The preparation of erbium-doped semiconductor materials in the nanometer scale is recently in progress to yield both high efficiency and speed of light emitters based on the electroluminescence induced by the Er^{3+} -intra-4f-shell transition, $^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$, near the wavelength equal to $1.54\mu\text{m}$ that corresponds to minimal losses in optical fibers. Porous Si [1] and quantum dots in self-assembled silicon quantum wells (SQW) [2] that are doped with erbium appear to provide a spatial confinement of non-equilibrium electrons and holes near the erbium-related centres to enhance the excitation of the Er^{3+} -ions. Besides, the Er^{3+} -related intracentre luminescence is enhanced from the ions incorporated into the microcavities tuned in the range of the $^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$ transitions [3]. Here we report on high efficient electroluminescence from erbium doped SQW that are embedded in silicon microcavities revealed by

the transmission spectra, which is caused by strong coupling the Er^{3+} -ion f-electron states to the s-p electronic states of the host nanostructure.

2. Methods

The silicon (100) wafers of the n- and p-type were doped with erbium in the process of long-time diffusion accompanied by surface injection of vacancies. Erbium doping was done at the diffusion temperature of 1100°C on the working side of the wafers after covering the oxide overlayer with a mask and performing the subsequent photolithography. Then, short-time diffusion of boron and phosphorus was performed at the diffusion temperature of 800°C from gas phase under fine surface injection of primary defects, which leads to the ultra-shallow p^+-n and n^+-p junctions ($\cong 10\text{nm}$) controlled using the SIMS and STM techniques.

The cyclotron resonance (CR) angular dependencies show that the p^+ - and n^+ -diffusion profiles consist of SQW divided by heavily doped δ -barriers (Fig. 1). Besides, the self-assembled microdefects of the self-interstitials type that penetrate through the p^+ - and

Fig. 1. The energy band diagram of ultra-shallow silicon p^+-n (a) and n^+-p (b) junctions that consist of quantum wells divided by heavily doped δ -barriers.

n^+ -diffusion profiles are found to be prepared by the oxidation and subsequent short time impurity diffusion (Fig. 2). The STM images obtained demonstrate the self-organization of these microdefects in the microcavity system that exhibits a distributed feedback identified by the FIR transmission spectra (Fig. 3).

3. Results

The erbium doped SQW embedded in microcavities obtained were studied using the magnetic susceptibility

Fig. 2. STM images of the ultra-shallow boron diffusion profiles prepared at diffusion temperature of 800°C into the Si(100) wafer covered previously by thin oxide overlayer. $X \parallel [001]$, $Y \parallel [010]$, $Z \parallel [100]$.

and FIR transmission and electroluminescence techniques. The erbium-related centres inside the SQW have been found to represent the molecular defects, in which the antiferromagnetic erbium pairs bound by the exchange interaction through the action of valence electrons from three oxygen atoms [2]. The temperature and magnetic field dependencies of the magnetic susceptibility demonstrate that the antiferromagnetic erbium pairs being incorporated into SQW exhibit the Van-Fleck paramagnetism enhanced by the interplay between the spin correlations and the electron–vibration interaction [2].

The optically induced intraband transitions in the p -type strongly coupled SQW (Fig. 1a) that are revealed by the angular dependencies of the Rabi splitting in the transmission spectra are observed to cause the Auger excitation of the $^4I_{13/2} \rightarrow ^4I_{15/2}$ Er^{3+} -intracentre absorption (Figs. 3 and 4). The SQW strong coupling seems to be due to the built-in electric field of the ultra-shallow p^+-n junctions which results in the Keldysh effect that is responsible for the spread of the resonance wavelengths up to 1.6 μm (Fig. 3d). Besides, built-in electric field gives rise to the Stark effect that perturbs p - f mixing caused by the 2D hole localisation on the Er-related centres incorporated into SQW [2]. This spatial confinement of the p -states and the localized f -electron states has to be enhanced by the SQW squeezing, which leads to high absorption efficiency at room temperature without any quenching that is a direct consequence of the enlarged range between quantum dimensional states (Figs. 3d and 4). Therefore, the utmost in effective energy transfer is observed owing to the SQW width equal to 2 nm, when the s - p -electron bandgap value is found as being equal to 2.6 eV, that allowed to record the high efficient $^4I_{13/2} \rightarrow ^4I_{15/2}$ electroluminescence from the n -type strongly coupled SQW (Fig. 1b) which is

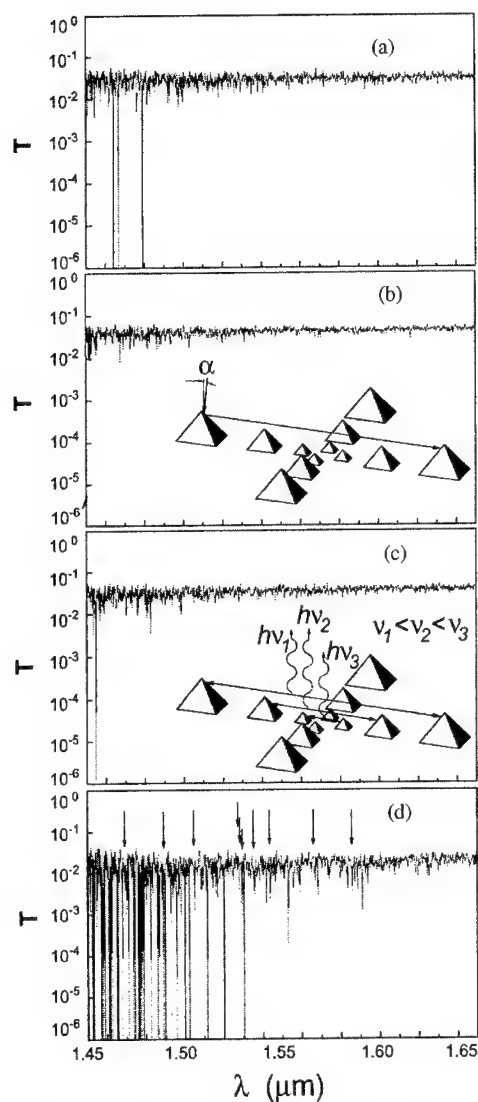

Fig. 3. The transmission spectra measured at different angles between the normal to the Si(100) surface and the light beam, α , that causes the $^4I_{13/2} \rightarrow ^4I_{15/2}$ Er^{3+} -intracenter absorption in the p-type erbium doped SQW embedded in the silicon microcavity. (a) $\alpha = -8^\circ$ (b) $\alpha = +2^\circ$ (c) $\alpha = +7^\circ$ (d) $\alpha = +17^\circ$. The inserts in (b) and (c) depict the model of self-assembled microcavity systems, respectively, in the regimes of the absorption and emission.

characterised by the Er^{3+} -multiplet structure (Fig. 5a). The number of observed EL lines corresponds to the trigonal symmetry of the Er-related centre (Fig. 5b) [2,4]. The $^4I_{13/2} \rightarrow ^4I_{15/2}$ electroluminescence is induced by the application of the reverse bias to the n^+-p junction that causes the electron tunneling from the valence band through the n-type SQW series (Fig. 1b).

Fig. 4. Spectral dependence of the light transmission coefficient through the p-type erbium doped SQW embedded in the silicon microcavities tuned in the range of the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transitions.

This resonant tunneling is accompanied by the cascade emission which is a basis of the EL excitation which is also enhanced by the Stark effect that appears to mix the Er^{3+} f-states and the s-states of the SQW. Besides, the resonant electron tunneling through the SQW series results in an oscillating character as a function of the electric field value [2]. The EL oscillations are followed by the electron quantum confinement determined by the dimensions of the silicon nanostructures [2].

4. Conclusions

The high efficient absorption and emission found in the erbium doped silicon self-assembled quantum wells

Fig. 5. embedded in the microcavity revealed by the transmission spectra has been shown to be due to a fast energy transfer into the 4f-shell transitions of the Er^{3+} -ions that is caused by strong sp-f mixing in built-in electric field.

Erbium in Si and GaN: extended versus point defects

P.H. Citrin*, D.R. Hamann, P.A. Northrup

Bell Laboratories, Lucent Technologies, Room 3L-403, 600 Mountain Avenue, Murray Hill, NJ 07974, USA

Abstract

Extended X-ray absorption fine structure measurements show that Er defects in O-poor Si closely resemble bulk Er_3Si_5 with long Er–Si bonds, while in GaN, regardless of O content, Er substitutes for Ga sites as point defects with unusually short Er–N bonds. The structure and energetics of these two systems were examined in a series of density functional theory calculations. The detailed findings and excellent agreement with the data provide new insight into the origin of this very different Er-doping behavior. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Er-doped Si; GaN; EXAFS; Density functional theory

Erbium as a dopant in semiconductor hosts has been studied for more than 15 years [1–4], yet some of the most basic information about the Er structures remains controversial or unexplained. Does Er occupy interstitial or lattice sites in the form of point defects, or are the defects extended in the form of precipitates? How does the formation of Er defects depend on the specific semiconductor host and on the conditions of sample preparation, e.g., epitaxy versus ion implantation, Er concentration, or O impurities? Knowing the type of defect formed, what is its structure?

This paper addresses each of the above questions for the case of two Er-doped semiconductors, Si and GaN, and in the process reconciles a number of conflicting results reported for Er defect structures [5–11]. Our approach uses a combination of extended X-ray absorption fine structure (EXAFS) measurements, density functional theory (DFT) calculations, and simple chemical considerations. Where appropriate, we also make reference to scanning transmission electron microscopy (STEM) measurements discussed in a more extensive study [12]. We find that in O-poor Si, the formation of Er–Si point defects is energetically prohibitive and experimentally not observed.¹ Erbium

in Si forms, instead, extended defects of ErSi_{2-x} platelets, whose structure depends largely on Er concentration. By contrast, Er in GaN occupies Ga sites as point defects whose formation is insensitive to the abundantly present O. We argue that the difference in types of defects observed in Si:Er versus GaN:Er is traceable to the chemical/energetic differences between the metallic Er–Si and ionic Er–N bonds.

The samples measured here were grown by molecular beam epitaxy (MBE) and are the same ones used in previous studies [13,14]. Two Si:Er samples [13] consisted of 0.1- μm -thick films, deposited in a $<5 \times 10^{-11}$ Torr base pressure onto Si(100) substrates at 600°C, with total Er doses of $9 \times 10^{13} \text{ cm}^{-2}$ and $5 \times 10^{14} \text{ cm}^{-2}$. They are referred as high- (*H*) and low-dosed (*L*) samples. Meaningful volume concentrations cannot be established because strong Er surface segregation was observed, i.e., the Er density is non-uniform. The GaN:Er samples [14] consisted of 2.5- μm -thick films, grown on Si(111) substrates at 750°C, with effective volume concentrations ranging between $1\text{--}3 \times 10^{20} \text{ cm}^{-3}$ for Er and $5 \times 10^{18}\text{--}5 \times 10^{20} \text{ cm}^{-3}$ for O. Erbium L_3 -edge absorption measurements were performed at the NSLS using the Bell Laboratories X15B beamline [15]. Samples were cooled $<60 \text{ K}$ to minimize effects of thermal disorder, and data were obtained using Er $L_3\alpha$ fluorescence yield detection.

Theoretical calculations of the structure and energetics of Er in Si were carried out with the pseudopo-

¹ In O-rich Si, where Er getters O, point defects of ErO_6 -like structure are formed, cf., Ref. [6].

tential plane wave method implemented as Car-Parinello molecular dynamics [16]. The generalized gradient density functional of Perdew, Burke, and Ernzerhof (PBE) [17] was adopted because of its demonstrated ability to produce accurate structural energy differences. The Er pseudopotential was constructed using the electronic configuration $[\text{Xe}]4f^{11}5d^16s^2$ for the all-electron atom and treating the 4f electrons as part of the core using the generalized norm-conserving approach [18]. Non-linear core corrections [19] were included in the exchange-correlation energies. Brillouin zone samples were constructed following the Monkhorst and Pack [20] method, and convergence was tested for representative samples of the various structures considered. A cutoff of 18 Ry for the plane wave basis yielded excellent convergence of structural energy differences.

Fig. 1 shows Fourier transform (FT) regions of the Er L_3 -edge absorption data from the GaN:Er and Si:Er samples and the model compounds ErN and Er_3Si_5 . For clarity, only first nearest-neighbor shells are displayed. Qualitative comparison between the two Er-doped systems is striking, with the first-neighbor bond lengths differing by as much as $\sim 0.8 \text{ \AA}$. Using standard procedures [21] and relevant distances in model compounds, we find the average Er–Si distance in Si:Er is almost 3 \AA long while the Er–N distance in GaN:Er is the shortest measured bond length between Er and any other atom, including H.

Focusing first on Er-doped Si, the filtered, back-transformed EXAFS from the Er–Si shell in the *H* sample of Si:Er (*L* is very similar) is compared with that of Er_3Si_5 in Fig. 2. The Er–Si distance, R , is $\sim 0.04 \text{ \AA}$ longer in Si:Er, and the first-neighbor coordination, N , is $> 80\%^2$ of that in Er_3Si_5 .

A reliable local structure for Er_3Si_5 is needed to quantify R and N in Si:Er. Calculations for bulk Er_3Si_5 were carried out, which proved important beyond obtaining local structure. The results tested the overall accuracy of our methods by comparison with X-ray diffraction data [22], and provided an energy reference so that energies of Er defect structures could be presented relative to the phase-separated bulk materials. As shown in Fig. 3, Er_3Si_5 is a vacancy superlattice based on the AlB_2 structure with one of 6 Si missing from each graphitic-like Si layer [23]. This structure was optimized, yielding lattice parameters that are within 1% of experiment [22]. Internal relaxations relative to the hypothetical ErSi_2 structure in Fig. 3 were found to be substantial, with the 3 Si around the vacancy moving

Fig. 1. Selected Fourier-transformed (FT) EXAFS data from Er doped in GaN and Si, along with model compound data. For clarity, only first-neighbor FT peaks are shown.

Fig. 2. Filtered EXAFS data from back-transforming the Er–Si FT peaks in Fig. 1. Also shown are simulated Er_3Si_5 data using Er–Si distances calculated here.

inward an average of 0.43 \AA . Such distortions result in a broad distribution of Er–Si bond lengths, $2.88\text{--}3.32 \text{ \AA}$. The individual bond lengths, unavailable from powder diffraction data [22], were used as input for the simulated EXAFS spectrum shown in Fig. 2, giving excellent agreement with experiment. For sample *H*, an average R of $2.97 \pm 0.04 \text{ \AA}$ and $N > 6.5$ are obtained (note that these values are not arithmetic means because nearer shells are preferentially weighted in EXAFS [21]).

Sample *H* was investigated with STEM [12] and found to contain (as originally suggested [13]) silicide precipitates within the film. Additionally, precipitates were found very near the surface where Er had segregated. Sample *L* showed similar signs of predominant silicide precipitates near the surface, but none were found within the film. These results explain why the EXAFS from *L* (not shown) closely resembles that from *H*, and why both *H* and *L* samples resemble Er_3Si_5 . If point defects are present in *L*, they are below experimental detection with STEM.

²This is a lower limit on N because a large fraction of the surface-segregated Er (Ref. [13]) is oxidized upon air exposure, so the total Er absorption used in normalizing N actually reflects coordination to both Si and O (the Er–O FT peak at $R' \approx 1.8 \text{ \AA}$ is not shown in Fig. 1).

Table 1

Energies and geometries of extended and point Er–Si structures in order of increasing energy. Δ is the energy per Er referenced to the separated phases of bulk Er_3Si_5 and Si, N is the Si coordination around Er, and R_{avg} is the average Er–Si distance

	Configuration	Δ (eV)	N	R_{avg} (Å)
Bulk	Er_3Si_5	0	10	3.03
	ErSi_2	0.3	12	3.06
Extended 2D Structures	Er–Si _{VAC} –Er bilayer (closed)	0.3	9	3.01
	Er–Si _{VAC} –Er bilayer (hollow)	0.6	8	3.01
	Er monolayer (closed)	0.7	8	3.01
	Er–Si–Er bilayer (hollow)	0.9	9	3.01
	Er monolayer (hollow)	1.2	6	3.01
Point Defects	Er–(vacancy) ₂	3.9	6	2.91
	Er–vacancy	4.3	10	2.96
	Er _{tetr.} interstitial	4.6	10	2.72
	Er _{substitutional}	4.6	4	2.70

Since point defects must exist in the dilute limit, it is natural to ask what the concentration limit is before Er silicide precipitates. Surface segregation for MBE-grown samples at 600°C limits this maximum concentration to $\leq 2 \times 10^{19} \text{ Er/cm}^3$ [13], while Er diffusion upon annealing ion-implanted samples at 900°C for 30 min limits this to $\leq 5 \times 10^{17} \text{ Er/cm}^3$ [12]. Significantly, previous structural work on Er-doped Si [5,6,8–11] all looked at samples with Er concentrations in excess of these limits, meaning that it is the structure of Er in silicide precipitates, not point defects (see footnote 2), which has been studied thus far.

In addition to kinetic processes, it is important to consider the energetics of forming Er point defects. A series of such defects was constructed using a cubic 64-atom Si supercell. For the tetrahedral interstitial, attempts to relax the Er site symmetry to C_{3v} failed, leading back to the T_d symmetry imposed in previous work [7]. This structure, substitutional Er, Er paired with a Si vacancy, and Er centered between a near-

neighbor pair of Si vacancies all yielded very large energy penalties, see Table 1.

We next studied the energetics of extended Er defect structures resembling silicides. Our model calculations used trigonal supercells containing 15–53 atoms, with the a lattice parameter constrained to that of bulk Si and the c lattice parameter and all internal coordinates free to relax. Silicide precipitates are observed to grow as (111)-oriented platelets [12,24], so our models contained Er sheets between Si (111) double layers. Results for the different structures are summarized in Table 1. Two models of Er monolayers are shown in Fig. 4, one centered over “hollow” sites and one over “closed” sites in the buckled Si bounding layers. These had 70–85% lower energies than any of the point defect models. The Er bilayer models had even lower energies. Centering Er over closed rather than hollow Si sites resulted in energy reductions of 0.5 and 0.3 eV for the Er monolayer and bilayers, respectively. Introducing vacancies in the quasi-graphitic Si layer between the Er bilayer gave an

Fig. 4. Comparison between two extended defect structures resembling Er silicide. For clarity, bonds between Er (dark balls) and Si are omitted.

additional 0.3 eV reduction, paralleling the bulk Er_3Si_5 result.

Strong support exists for our calculated structures. STEM data from the MBE-grown sample *H* show Er monolayers in silicide-like precipitates with a noticeable absence of stacking faults in the Si network surrounding the platelets [12], while samples implanted with higher concentrations of Er show larger bilayer structures and clear evidence of stacking faults [12,24]. The only configuration satisfying these conditions for both the monolayer and bilayer structures is the one with Er centered over closed-sites, which we calculate for each to have the lowest energies.³

Looking at Er-doped GaN, we find that Er behaves completely differently than in Si. EXAFS data show [14] that Er occupies Ga sites as point defects up to concentrations $\geq 10^{21} \text{ Er/cm}^3$, that such defects are insensitive to similarly high O concentrations, and that the Er–N bond length of $2.17 \pm 0.02 \text{ \AA}$ is shorter than in bulk ErN by 0.25 Å.

Our theoretical methods required modifications to deal with the highly localized N valence electrons and the more localized Ga semi-core d electrons, which behave as valence electrons in the presence of N. Convergence required the use of adaptive curvilinear coordinates [26] and references therein, boosting average plane wave cutoffs of 50 Ry to a maximum value of 212 Ry where needed. A 48-atom rhombohedral supercell was constructed using the theoretically optimized GaN lattice parameters, with Er substitution on one Ga site. A relaxed Er–N bond length of 2.20 Å was obtained, 1.5% larger than the EXAFS result and consistent with the 1.6% PBE overestimate of the GaN lattice parameters. In strong contrast to the Er–Si point

defects, the energy penalty here relative to phase-separated bulk ErN and GaN was only 1.2 eV.

The high energies of the Er point defects in Si are relatively independent of coordination number and bond length (see Table 1). We suggest that the much lower energies of the extended defect structures (and of Er_3Si_5) arise from indirect metallic Er–Er bonding mediated by Si layers [12]. Because of the ionicity of the ErN and GaN:Er systems [14], this energy lowering mechanism is not available, reducing the possible energy that could be gained by segregating ErN platelets or clusters. Therefore, only direct, ionic Er–N bonds need be considered, and bond number versus bond strength (and length) arguments [14] are consistent with the short bonds and small energy penalty calculated here for the Er point defects in GaN.

Acknowledgements

We thank A. Polman and A.J. Steckl for the Er-doped Si and GaN samples, respectively, and M.J.A. de Dood for helpful discussions about the MBE-grown Si:Er. The X-ray absorption measurements were performed at the NSLS, Brookhaven National Laboratory, which is supported by the DOE, Division of Materials Science and Division of Chemical Sciences.

Abstract

Er doped nc-Si thin films have been investigated by spectroscopic ellipsometry (SE). The optical response of Er ions in a nc-Si/SiO matrix has been determined by SE, and it has been used to detect Er contents as low as ~ 0.2 at%. The complex layered nanostructure of nc-Si:Er:O has been resolved and it has been found that it is strongly influenced by the Er-doping and the oxygen in-depth distribution profile. SE results are discussed in comparison with data obtained by the standard methods of the X-ray diffraction, Rutherford backscattering and Raman spectroscopy. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Spectroscopic ellipsometry; Nanocrystalline silicon; Erbium

1. Introduction

Erbium doped nanocrystalline silicon, nc-Si:Er, thin films produced by RF magnetron sputtering have been reported to be effective emitters at the 1.54 μm wavelength (corresponding to the intra-4f transition of Er^{3+} ions) in a wide temperature range from 5 to 300 K [1]. Hence, they are attractive for applications in Si-based optoelectronic devices. However, the Er luminescence intensity in nc-Si thin films is strongly influenced by the complex nanostructure of films, i.e. the nanocrystalline volume fraction and crystallite size, and by the impurity content (mainly oxygen). Hence, it is important a detailed investigation of the “anatomy” of the nc-Si:Er,O films, i.e., the layered structure, the non-homogeneous distribution of the nc-Si and a-Si phases, and the in-depth distribution of the SiO phase, which are strongly dependent on the growth conditions.

In this contribution, the nanostructure of nc-Si:Er,O thin films deposited by the RF magnetron sputtering is analyzed by spectroscopic ellipsometry (SE). By the SE technique, the optical response of Er ions in a nc-Si/SiO matrix has been determined and used to evaluate Er contents as low as 0.2 at% in the layers. Additionally, SE analysis reveals the complex layered structure and impurity distribution in nc-Si:Er,O films, whose optical response is described by the Bruggeman effective medium approximation (BEMA). In contrast, data obtained by X-ray diffraction and Raman spectroscopy only provide the average value of the crystallinity over the whole film thickness. The effect of the Er content on the structure of nc-Si thin film is discussed.

2. Experimental

Erbium doped nanocrystalline silicon thin films were grown on glass substrates by the reactive magnetron sputtering in H_2/Ar atmospheres with various H_2 percentages. The target was a c-Si wafer where some pieces of high purity (99.99%) metallic erbium were

*Corresponding author. Tel.: +39-80-5443562; fax: +39-80-5442024.

E-mail address: cscpm18@area.ba.cnr.it (M. Losurdo).

added for the doping. Growth parameters, such as the temperature, T_{gr} , the RF power, and the type of atmosphere (hydrogen or argon rich) were varied to obtain films with different Er-, H- and O-content and different crystallinity and nanocrystal grain sizes, as shown in Table 1.

Spectroscopic ellipsometry measurements of the complex pseudodielectric function $\langle \epsilon \rangle = \langle \epsilon_1 \rangle + i\langle \epsilon_2 \rangle$ of the films were performed in the range 1.5–5.5 eV. SE measured the energy dependence of the ellipsometric angles Ψ and Δ , and, hence, of the ratio, ρ , between the complex reflectance coefficients of two components of

the polarized light, r_p , and r_s , respectively, parallel and perpendicular to the plane of incidence, according to the equation:

$$\rho = r_p/r_s = \tan \Psi \exp(i\Delta), \quad (1)$$

where Ψ is the amplitude ratio ($\tan \Psi = |r_p|/|r_s|$), and Δ is the phase difference ($\Delta = \delta_p - \delta_s$) between the p and s components. The pseudodielectric function, $\langle \epsilon \rangle$, was derived from the ρ parameter through the following equation [2]:

$$\langle \epsilon \rangle = \epsilon_0 \sin^2 \phi_0 [1 + \tan^2 \phi_0 (1 - \rho)^2 / (1 + \rho)^2], \quad (2)$$

^a Here T_{gr} is the growth temperature; RH determines the hydrogen fraction in growth atmosphere derived from the ratio of partial pressures $RH = p_{H_2}/(p_{H_2} + p_{Ar})$; RF is the RF magnetron power; d is the thickness of the films, determined from the transmission spectra in UV-visible range; Er, O, and Si are elements content obtained by RBS method; D_x and ϵ_x are nc size and strain, determined by XRD method, D_R and c_R are the grain size and crystallinity of the films measured by Raman spectroscopy.

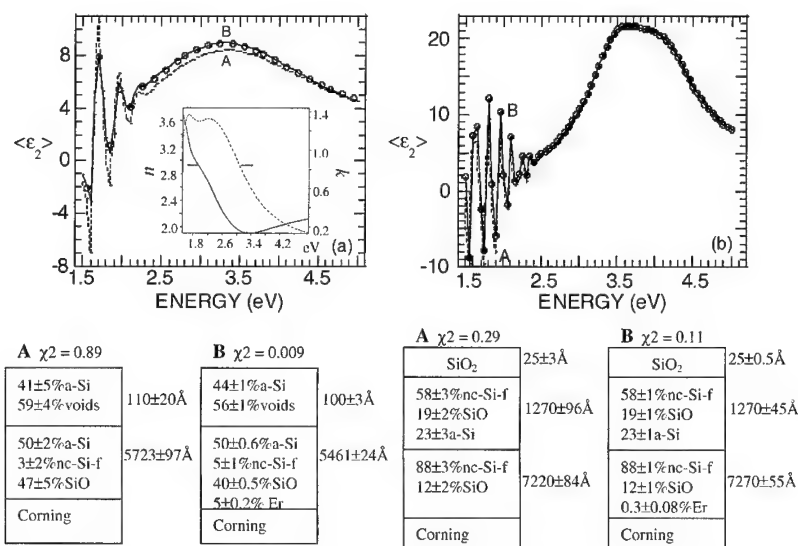

Fig. 1. SE spectra of the imaginary part, $\langle \epsilon_2 \rangle$, of the pseudodielectric function of samples with (a) high (sample Er3) and (b) low (sample Er12) Er-content. Fit results according to BEMA models with (continuous lines; models B) and without (dashed lines; models A) Erbium inclusion are also shown together with the corresponding BEMA models. The inset shows the optical response (in terms of the refractive index n and extinction coefficient k) of Er ions in the nc-Si/SiO matrix as determined by the least-squares regression analysis using a Lorentzian oscillators based dispersion equation in the high doped sample. The fit goodness, χ^2 , and 95% confidence limits of fit parameters are also shown.

where ϕ_0 is the angle of incident light and ϵ_0 is the ambient dielectric function.

SE spectra were analyzed in terms of optical models based on the Bruggeman effective medium approximation (BEMA) [3] applying the least-squares regression method for the fitting, where the fit goodness was estimated by the parameter χ^2 [4]. The 95% confidence limit of fit parameters was also evaluated. The dielectric function of a-Si, nc-Si-fine grains, nc-Si-large grains and silicon oxides (SiO_2 , SiO_x , SiO) reported in Ref. [5] were used in the BEMA analysis. SE studies were referred by measurements of transmission spectroscopy for the evaluation of the film thickness and accompanied by the measurements of RBS, XRD and Raman spectroscopy presented in Table 1.

3. Results and discussion

Fig. 1a shows the experimental SE spectrum of the imaginary part, $\langle \epsilon_2 \rangle$, of the pseudodielectric function of a nc-Si:ErO film whose RBS analysis gave an Er content of 4.7% (sample Er3). Different BEMA models have been tested in the fit analysis of this spectrum. It can be seen in Fig. 1a that a two-layer model (model A; dashed curve) which only considers the amorphous, crystalline silicon and SiO components does not provide a good fit, resulting in high values of the fit goodness parameter, $\chi^2 = 0.89$, and of 95% fit parameters confidence limits. Therefore, we concluded that the discrepancy in the calculated spectrum parameters could be related to the unaccounted response of Er impurity. Indeed, after introducing in the BEMA model a dispersion relation based on Lorentzian oscillators describing the dielectric response of erbium ions, a perfect fit, with lower $\chi^2 = 0.009$ and lower errors on fit parameter (layer thickness and constituent volume fractions), was obtained (model B; solid line), yielding a volume fraction of Er of about 5% (see model B), in excellent agreement with the RBS results. The determined dielectric response of erbium ions in a nc-Si/ SiO matrix used for the fitting models is shown in the inset of Fig. 1.

The sensitivity of SE to the Er content was also tested in samples with low Er-contents ($<1\%$). Fig. 1b shows the experimental and fit spectra for a sample with 0.2% of Er, as determined by RBS (sample Er12). By the inclusion of a 0.3% volume fraction of Er ions, the fit goodness parameter χ^2 decreases by a factor 3, and also errors on fit parameter decrease (see best fit BEMA models). In this case, the contribution of Er to the fit improvement is better seen in the low energy region (below 2.5 eV) where the optical response of Er reveals the strong absorption (see inset in Fig. 1a). It is worthy to note that the estimations of concentration performed by SE analysis are in good

accordance with the RBS values not only for Er but also for O atoms (compare the models and the values in Table 1).

A strong influence of the Er-doping on the nanostructure and optical properties of thin nc-Si films has been found. Fig. 2 contrasts the $\langle \epsilon_2 \rangle$ spectra of nc-Si films grown in identical conditions with (samples Er12 and Er13) and without (samples Si12 and Si13) Er-doping. The #12 and #13 samples only differ in the growth temperature of 350°C and 250°C, respectively. The comparison of SE spectra obtained for both sets shows that the inclusion of Er increases the amplitude of the pseudodielectric function, smoothes and nears the

Fig. 2. SE spectra of the imaginary part, $\langle \epsilon_2 \rangle$, of the pseudodielectric function of samples with (Er12, Er13) and without (Si12, Si13) erbium inclusion. The best-fit results according to BEMA models are presented at the bottom. The fit goodness, χ^2 , and 95% confidence limits of fit parameters are also shown.

energetic position of the characteristic E_1 and E_2 peaks, which are indicative of the presence in films of the crystalline fraction [6]. The characteristic E_1 and E_2 peaks (at about 3.4 and 4.2 eV, respectively) become more pronounced in the spectra of undoped samples. Qualitatively, this spectral behavior provides indication on a larger grain size for undoped films, while smaller silicon grains are present in Er-doped films. In fact, the BEMA models of the undoped Si12 and Si13 samples include, in the inner and outer layers, the dielectric function of nc-Si-large grains, while the response of Er doped samples is mainly represented by the dielectric function of nc-Si-fine grains (the best-fit BEMA models obtained for these samples are presented at the bottom of Fig. 2.). This effect of the Er-content on the grain size has been confirmed by the X-ray diffraction measurements reported in Table 1, which reveal a strong (about 2 times) decrease of the grain size in samples doped with Er, so corroborating the SE results. In contrast, no variation of the grain size was detected by Raman. However, this apparent discrepancy is explained by the fact that the Raman method only probes the thin near-surface layer (within the second outer layer in the BEMA models) in the film, where the low-size crystal grain fraction dominates. Therefore, SE is sensitive to structural aspects, such as the different crystalline fraction and grain size in the different layers constituting the nc-Si:Er:O films, which otherwise cannot be resolved by XRD and Raman. In addition, SE data show that the larger grain size accompanies with a larger inclusion of the SiO component, since oxygen segregates at the grain boundaries (see Er12/Si12 samples in Fig. 2). It is thought that this Er effect on the grain size could be related to the preferential incorporation of Er ions into interstitial sites of the silicon network, so causing distortion of the lattice periodicity and

obstructing the crystal grain expansion during growth. However, further work is in progress to understand the mechanism of the evolution of nc-Si film structure with Er-doping.

4. Conclusions

Spectroscopic ellipsometry has been applied to the analysis of the nanostructure and chemical composition of Er-doped nc-Si thin films, produced by the RF magnetron sputtering. In contrast to the standard techniques of X-ray diffraction, Rutherford backscattering and Raman spectroscopy, which provide averaged structural and compositional data, ellipsometry reveals the complex layered structure and impurity distribution in nc-Si:Er:O films. It has been found that the inclusion of Er in nc-Si thin films lowers the Si crystallite sizes in nc-Si thin films. Additionally, SE shows a surprisingly high sensitivity to the Er content as low as 0.2 at%. The optical response of Er ions in a nc-Si/SiO matrix has also been determined.

Determination of the atomic configuration of Er–O complexes in silicon by the super-cell FLAPW method

M. Hashimoto*, A. Yanase, H. Harima, H. Katayama-Yoshida

Department of Condensed Matter Physics, The Institute of Scientific and Industrial Research, Osaka University, Osaka 567-0047, Japan

Abstract

We determined the atomic configuration of Er–O complexes in silicon from the first principles using the super-cell FLAPW method within the local density approximation. We proposed two models of the atomic configuration of Er–O₆ complexes in silicon with C₂ symmetry, one is stable and the other is meta-stable in the thermal equilibrium conditions. Our proposed atomic configurations of Er–O₆ complexes are consistent with the experimental results of EPR and EXAFS measurements, which reported the existence of several stable and meta-stable low-symmetry centers and similarity to the C₂-symmetry center of the Er₂O₃. © 2001 Elsevier Science B.V. 1. Introduction

Erbium (Er) doped semiconductors attract much attention because of their sharp and temperature independent luminescence caused by intra-4f transition. These materials are expected to be applied to temperature-independent optoelectronic devices. One of the possible applications is optical fiber communication because of the sharp emission of intra-4f transition emitting 1.54 μm -wavelength-light which matches the minimum absorption rate of the light in silica-based optical fibers. Especially Er doped silicon (Si), which is the leading semiconductor in microelectronic applications, is a promising material to achieve fully Si-based optoelectronics.

Experiments performed until 1993 had shown that the low solubility of Er in Si prevents the incorporation of high Er concentrations. This difficulty was overcome by the co-doping method (co-doped with Er and oxygen (O)) in 1993 [1]. The improvement in the solubility of Er was due to the reduction of formation energy by forming Er–O complexes. However the structures of the com-

plexes are still not well understood. Extended X-ray absorption fine-structure (EXAFS) showed that the Er impurity is surrounded by a cage consisting of 4–6 O atoms [2]. Electron paramagnetic resonance (EPR) measurement revealed that the Er atom is surrounded by 6 O atoms and forms several low-symmetry impurity complexes; four Er–O complexes exist before annealing and two Er–O complexes do after annealing [3]. So far, precise atomic configurations of Er–O have not been reported in theory or experiment.

In this study, we performed ab initio calculations in order to determine the atomic configurations of Er–O complexes in Si. We propose two models of different atomic configurations of Er–O complexes in Si based upon the total energy calculation, one is stable and the other is meta-stable. As far as we know, this is the first clarification of concrete atomic configurations of Er–O complexes in Si based upon ab initio electronic structure calculations.

2. Models and calculation

Calculations of the electronic structure and total energy are performed by using the full-potential linearized augmented-plane-wave (FLAPW) method

E-mail address: hashimoto@cmp.sanken.osaka-u.ac.jp (M. Hashimoto).

based on the local density approximation (LDA) [4]. For the exchange-correlation energy in the LDA, the analytical expression of Gunnarsson–Lundqvist is employed [5].

The angular momentum in the spherical wave expansion is truncated $l = 4$ and $l = 7$ for the potential and the wave functions, respectively. The cutoff energy of the plane wave is 19.42 Ry for the wave functions. We calculate the electronic structure and the total energy using only the point in the irreducible Brillouin zone, to achieve the self-consistency in the charge and the potential. The muffin-tin sphere radii for Er is chosen to be 1.116 and 0.576 for O and Si, respectively.

Rare Earth (RE) impurity in Si is taken into account by using super-cells containing 32 atoms. We use Lutetium (Lu) as RE impurity instead of Er since LDA does not estimate the exact states of open $4f^{11}$ shell in Er. The electron configuration of Lu is $4f^{14}5d^16s^2$ and it is ionized as Lu^{3+} with $4f^{14}$ closed-shell in a crystal. Since Er is ionized as Er^{3+} in the crystal and both $4f$ shell of Er and that of Lu are strongly localized around the nucleus, nucleus charge of Er and Lu are completely shielded by $4f$ electrons. Therefore the valence band of Lu is similar to that of Er.

3. Results and discussion

In order to determine the atomic configuration of the Er–O complexes in Si, first we investigated (1) the electronic structure and the most stable atomic configurations of isolated Er impurity in Si and next, (2) the most stable atomic configuration of isolated O impurity in Si. Finally, based on the above two atomic configurations, we investigated (3) the stable atomic configuration of Er–O complexes in Si.

We compared the total energy of the isolated Er impurity in Si located at the Tetrahedral (T_d) substitutional site and the T_d interstitial site. We found that the most stable atomic site of the isolated Er impurity in Si is at the T_d interstitial site (i.e. T_d interstitial site is 2.84 eV more stable than the T_d substitutional site). The stabilization of the Er impurity at the T_d interstitial site in Si is originated by the formation of the bond which are caused by the hybridization between Er-5d orbitals and the Si sp^3 orbitals [6].

We determined the atomic configuration of the isolated O impurity in Si. The most stable atomic site of O is at the off-bond-center site, where Si–Si bond length is 3.29 and O is located at the off-bond center site distorted 0.98 from the vertical line of the Si–Si bond.

In the calculation of (3), the models of the Er–O complexes were determined in the following way. We considered the Er impurity at the T_d interstitial site based on the stable atomic site of the calculated results of the isolated Er impurity. Next we considered the Er–

O complexes with 6 O atoms around the Er impurity at the T_d interstitial site, where O atoms are located at the Si–Si off-bond-center site based on the calculated results of the isolated O impurity. Twelve off-bond-center sites for O atoms are present around the Er impurity at the T_d interstitial site. We coordinated 6 O atoms at 6 of the twelve off-bond-center sites and picked up the low symmetry Er–O complexes from all possible atomic configurations because the EPR and EXAFS measurement indicate the low symmetry complexes in this system. These structures from our model have C_{2v} , C_2 and C_3 symmetry (the others have no symmetry). The structures are summarized in Fig. 1. We determined the stable atomic configuration of the Er–O complexes by comparing the total energy starting from these six Er–O complexes.

Fig. 1. Proposed models of atomic configuration of Er–O complexes in Si. The atom at the center of each figure is the Er atom. The white symbols indicate the Si atoms and the dark symbols indicate the O atoms. We show the symmetry and the atomic configuration of these complexes ((a) C_{2v} , (b) C_3 and (d)–(f) C_2). We label these complexes C_{2v} structure, C_3 structure, C_2 -A–D structures.

Fig. 2. The total energy difference between the possible candidates of six complexes (as defined in Fig. 1) measured from the most stable C_{2v} structure.

We show the calculated total energy differences in Fig. 2. From Fig. 2, we see that the most stable atomic configuration of the Er–O₆ complex is the C_{2v} structure followed by the C_{2-B} structure. The energy difference between them is 0.435 eV, therefore C_{2-B} structure is meta-stable in thermal equilibrium. The order of the stability is C_{2v} (0 eV) < C_{2-B} (0.435 eV) < C_{2-D} (1.292 eV) < C_{2-A} (1.577 eV) < C₃ (2.420 eV) < C_{2-C} (2.502 eV), where we showed the total energy difference measured from the most stable C_{2v} structure.

To obtain more stable structures of Er–O complexes, we applied an additional lattice relaxation to the two lowest energy structures (C_{2v} structure and C_{2-B} structure). The lattice relaxations were taken into account in the following procedures. First, we relaxed the 6 Si atoms around Er toward the Er atom while fixing the 6 O atoms. Next, we relaxed the 6 O atoms around Er while fixing the 6 Si atoms. As a result, we obtained more stable structures, Relaxed-C_{2v} (Fig. 3a) and Relaxed-C_{2-B} (Fig. 3b). The local configuration is the same for Relaxed-C_{2v} and Relaxed-C_{2-B} structure. We show the local structure of Er and O complex in Fig. 3c. This local structure and Er–O bond length is very similar to the structure of the Er₂O₃. The Er–O bond length of the local C₂ symmetry center of the Er₂O₃ is 2.26. The bond length of Er–O complex in Si reported in EXAFS measurement is 2.27 [2].

We evaluated cohesive energy E_{coh} by the following expression:

$$E_{\text{coh}} = E_{(\text{Er}, 6\text{O}, 32\text{Si})} - [E_{(\text{Er}, 32\text{Si})} + 6E_{(\text{O}, 16\text{Si})} - 48E_{(2\text{Si} : \text{host})}], \quad (1)$$

where $E_{(\text{Er}, 6\text{O}, 32\text{Si})}$, $E_{(\text{Er}, 32\text{Si})}$ and $E_{(\text{O}, 16\text{Si})}$ are the total energy for co-doping system, isolated Er impurity system and isolated O impurity system, respectively. $E_{(2\text{Si} : \text{host})}$ is the total energy for pure Si crystal and is introduced to correct the difference in the number of Si atoms between the first and the second term. We obtained $E_{\text{coh}} = -1.449 \text{ Ry} = -19.713 \text{ eV}$ with using

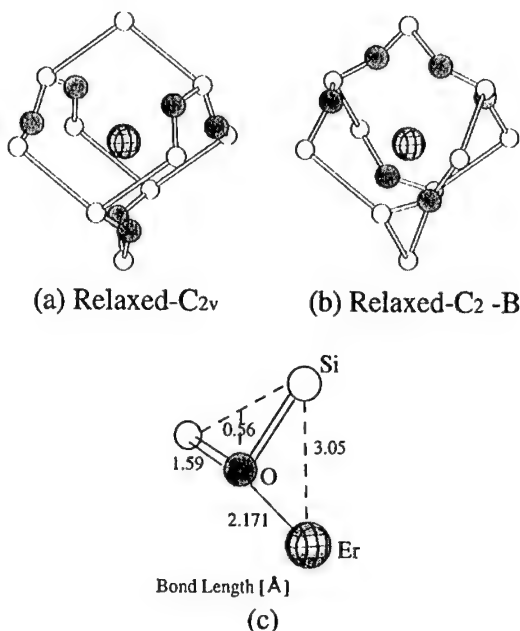

Fig. 3. The structures of the most stable two Er–O complexes (a) Relaxed-C_{2v} structure and (b) Relaxed-C_{2-B} structure. (c) The local structure surrounding the Er atom is also shown.

the calculated value of $E_{(\text{Er}, 6\text{O}, 32\text{Si})} = -48477.033 \text{ Ry}$ (for Relaxed-C_{2v}), $E_{(\text{Er}, 32\text{Si})} = -47595.990 \text{ Ry}$, $E_{(\text{O}, 16\text{Si})} = -9389.135 \text{ Ry}$ and $E_{(2\text{Si} : \text{host})} = -1155.317 \text{ Ry}$, respectively. We obtained a negative value of the cohesive energy indicating that the formation of the complex with 1 Er and 6 O atoms is stable and that we can observe this complex in thermal equilibrium condition. This indicates that the experimental result, which reported Er impurities forming complexes with six O atoms, is consistent with our theoretical calculations in the thermal equilibrium condition.

As mentioned before, various kinds of Er–O complexes exist in Si in the thermal non-equilibrium doping method such as ion implantation; four Er–O complexes exist before annealing and two Er–O complexes do after annealing. From our calculated result, the variation of Er–O complexes could be attributed to the several meta-stable states due to the difference of coordination of 6 O atoms. Our interpretation of the experiments based upon the present calculation is that the four lowest energy Er–O complexes should exist before annealing in Si (such as C_{2v}, C_{2-B}, C_{2-D} and C_{2-A}) and after annealing, four Er–O complexes convert to the two lowest energy Er–O complexes (C_{2v} and C_{2-B}). EPR and EXAFS measurements, similarity between Er–O complex in Si and the local C₂ symmetry center of the Er₂O₃ was reported. From our study, Relaxed-C_{2v} structure should correspond to the local C₂ symmetry center of Er₂O₃. Fig. 4 shows the O–Er–O angles of (a) the C₂

Fig. 4. The O–Er–O angles of (a) the C₂ symmetry center of the Er₂O₃, (b) Relaxed-C_{2v} structure and (c) Relaxed-C₂-B structure. Each angle is shown in the figures.

symmetry center of the Er₂O₃, (b) Relaxed-C_{2v} structure and (c) Relaxed-C₂-B structure. Since the trend of O–Er–O angles in the Relaxed-C_{2v} structure is similar to those of the C₂ symmetry center of the Er₂O₃, we conclude that these complexes have very similar atomic configurations. Determination of the local structure around Er impurity is essential for calculating the crystal field in the future by which we can predict the photoluminescence spectra of Er doped Si without using any adjustable parameters from experiments.

4. Summary

We studied the atomic configuration of Er–O complexes in Si by ab initio calculation using the FLAPW

method with super-cells based on LDA. We propose two possible candidates with different atomic configurations of Er–O₆ complexes in Si, one is stable and the other is meta-stable in the thermal equilibrium condition. Both of these complexes consist of one Er atom located at the T_d interstitial site and 6 O atoms at the Si–Si off-bond-center site. Both complexes have C₂ symmetry and one of these has similar atomic configuration to the local C₂ symmetry center of the existing Er₂O₃, which is consistent with the EXAFS and EPR measurements. Since the existence of several meta-stable Er–O complexes is proposed from the model, we conclude that the variation of these Er–O complexes come from the difference of the coordination of 6 O atoms around Er impurity, which agree very well with the result of the EPR measurement. We clarified the concrete atomic configuration of Er–O complexes in Si based on the ab initio calculation.

Study of Er-related defects in a-Si:H(Er)/c-n-Si heterostructures by thermally activated current spectroscopy

Ja. Vovk^{a,*}, A. Nazarov^a, V. Lysenko^a, O. Kon'kov^b, E. Terukov^b

Abstract

The paper is devoted to study of Er-related defects in electrical luminescence diode structures a-Si:H(Er)/c-n-Si, for which amorphous hydrogenated silicon film on crystalline Si substrate was fabricated both by plasma-enhanced chemical vapor deposition and magnetron-assisted silane-decomposition technique. Thermally activated current (TAC) spectroscopy by employing the thermally fractional cleaning method has been used. Observed TAC spectra have been shown to be weakly dependent on the film-deposited technique. It has been shown, that signal amplitude of the spectra increases, when Er concentration in a-Si:H increases. The traps with activation energies from 0.10 to 0.40 eV and from 0.5 to 0.6 eV have been charged both by light and thermal-bias stress, which allows to associate these with the deep levels in the band gap of the a-Si:H. The high-temperature current peaks with activation energies of 0.8–1.0 eV have been created only by thermal-bias stress and have been strongly dependent on the charging temperature. It has been suggested that these high-temperature thermally activated processes are related to polarization effects in the [Er–O] clusters, located in amorphous matrix of a-Si:H. The plausible origin of the observed deep levels and polarization processes is discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Amorphous hydrogenated silicon; Erbium; Deep levels

1. Introduction

Intensive investigations of electrical and optical properties of Er-contained semiconductor matrixes are linked, first of all, with light emission by intra-f shell transition at wavelength of 1.54 μm , which does not depend on the semiconductor matrix and is situated in the region of minimum absorption for quartz fibers. Incorporation of Er into silicon could result in effective connection of silicon-based electronic devices to optical communication systems. However, the limited solubility of Er in crystalline Si and rapid thermal quenching of the Er emission at room temperature [1,2] lead to unsatisfactory results.

In Ref. [3–5] effective room photo- and electroluminescence of Er ions in amorphous hydrogenated silicon (a-Si:H(Er)) have been observed. However, up to

now, the careful study of deep levels in a-Si:H(Er) has not been performed. In this connection, the paper is devoted to a study of charge trapping by deep levels related to Er in a-Si:H matrix of a-Si:H(Er)/c-n-Si electroluminescence diode.

2. Samples and experimental details

The erbium-doped amorphous hydrogenated silicon with thickness near 1 μm has been deposited on crystalline n-type Si substrate both by using the magnetron-assisted silane-decomposition (MASD) technique [6] and the plasma-enhanced chemical vapor deposition (PECVD) in a gas atmosphere containing 25% SiH_4 and 75% Ar [7]. In the case of the MASD technique, Er concentration was varied from 1×10^{18} to $1 \times 10^{20} \text{ cm}^{-3}$ and was uniformly distributed through the a-Si:H(Er) film. Oxygen concentration was determined by SIMS method and was equaled to an average of $1 \times 10^{21} \text{ cm}^{-3}$.

*Corresponding author. Fax: 380-44-265-6177.

E-mail address: nazarov@lab15.kiev.ua (J. Vovk).

In the case of the PECVD technique, Er was inhomogeneously distributed in the a-Si:H film with maximum concentration of about $1 \times 10^{21} \text{ cm}^{-3}$ located near the a-Si:H/c-Si interface. The average oxygen concentration was $5 \times 10^{21} \text{ cm}^{-3}$. The measurement structure was an Al/a-Si:H(Er)/c-n-Si/Al diode with aluminium contact approximately 1 mm in diameter (see inset in Fig. 1).

The study of energetic spectrum of electrical active traps in the a-Si:H(Er) material has been performed by thermally activated current (TAC) spectroscopy in the temperature range from 80 to 350 K with linear sample heating of 0.4 K/s. The traps in the a-Si:H(Er) layer were charged either by visible light and bias applied to substrate contact (V_s in the inset in Fig. 1) at 77 K or by bias applied to substrate at 320 K. Activation energies of discharging processes were determined by fractional

thermal cleaning method of the TAC spectra, proposed in Ref. [8]. The charge built up in the a-Si:H(Er) film after charging of the traps has been estimated by high-frequency (1 MHz) capacitance–voltage ($C-V$) characteristics measured at 77 K.

3. Experimental results and discussion

The TAC spectra measured in the heterodiodes fabricated by MASD technique are presented in Fig. 1. The charging of the structures has been performed at 320 K by bias applied with both positive and negative polarity. In this case, the TAC spectra are sufficiently symmetrical with respect to the temperature axis (Fig. 1b) and show that the current peaks in the

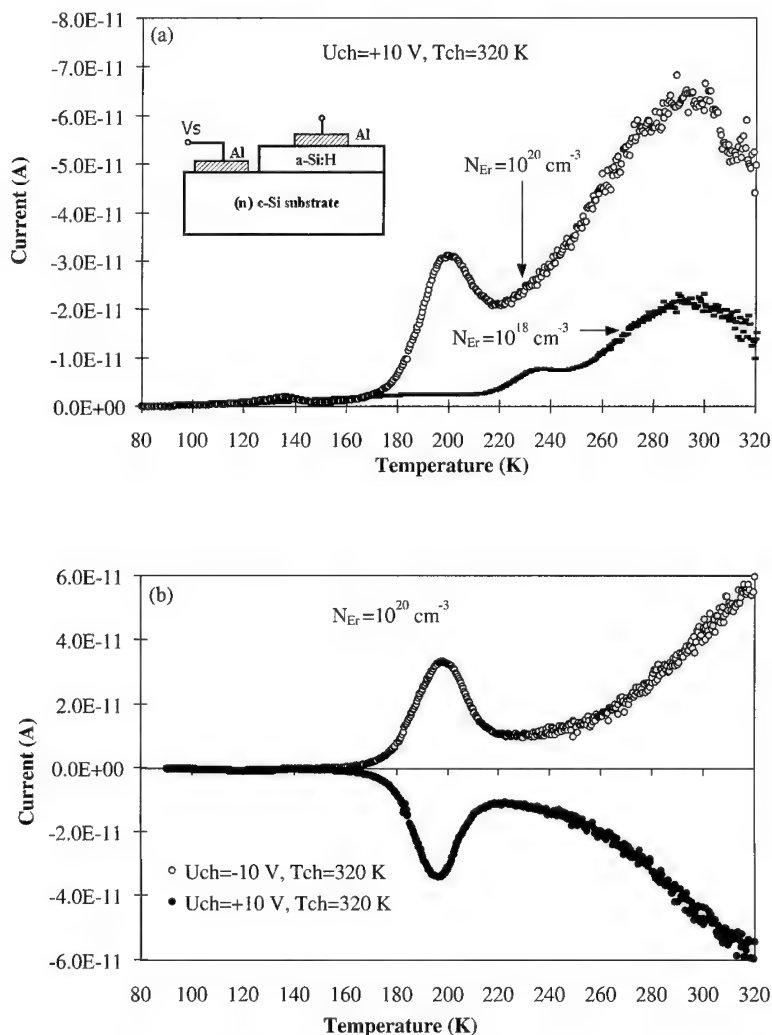

Fig. 1. Thermally activated current spectra of the Al/a-Si:H(Er)/c-n-Si heterodiode, fabricated by the MASD technique with different Er concentrations (a), and measured at different polarities of charging of the sample (b).

temperature range near 140, 190 and 230 K and from 290 to 340 K (Fig. 1a). Additionally, the increase of Er concentration results in the increase of TAC spectrum amplitude (Fig. 1a), that confirms a linkage of the observed current peaks with Er incorporation into the a-Si:H film. The structures containing Er and fabricated by PECVD method showed, principally, a TAC spectra similar to those obtained in the MASD samples (Fig. 2a). The initial structure, which contained no Er atoms in a-Si:H film, does not appear in any TAC peak in the temperature range from 140 to 340 K and current peaks of small amplitude have been observed in the temperature range from 80 to 140 K. Thus, we can conclude that all high-temperature TAC peaks in a-Si:H(Er)/c-n-Si structure are associated with Er incorporation into the a-Si:H matrix.

It should be noted that the effect of visible light and bias at liquid-nitrogen temperature leads to creation of

the TAC peaks only in the temperature range from 80 to 270 K both for the MASD and PECVD structures (see Fig. 2a). Thus, the TAC peaks, appearing in this temperature range, can be associated to the deep levels of charge traps located in the a-Si:H(Er) matrix.

The wide current peak observed in the temperature range from 270 to 340 K is created only in the case of charging the samples at temperatures above 260 K. The result observed is an evidence of the different nature of the high-temperature current peak from other low-temperature ones.

Measurement of $C-V$ characteristics before and after charging the structure by negative bias applied to substrate (forward bias) shows the net electron trapping in the a-Si:H(Er) film, whereas the charging by positive bias applied to the substrate (reverse bias) leads to the net hole trapping (Fig. 2b). Thus, a forward bias applied to the structure results in occupation of the deep levels

Fig. 2. Thermally activated current spectra (a) and capacitance-voltage characteristics (b) measured on the PECVD heterodiode.

located in the upper half of the a-Si:H band gap, whereas the reverse bias applied leads to the charging of the deep levels located in the bottom half of the band gap.

Results of fractional thermal cleaning of the TAC spectra obtained for positive and negative bias, applied to the substrate during the charging of the MASD structures at high temperatures, are presented in Fig. 3. The energetic levels of the obtained electron traps are the following: $E_c - 0.10$, 0.40 , 0.55 , and 0.60 eV. The hole deep levels are $E_v + 0.20$, $E_v + 0.30$, $E_v + 0.50$ and $E_v + 0.60$ eV. The deep levels $E_v + 0.50$ and $E_c + 0.55$ eV possess the maximum amplitude of the TAC (that is maximum concentration in comparison with other deep levels).

The processes with activation energy near 0.85 – 1.00 eV corresponding to the high-temperature current peak are probably associated to polarization processes in erbium-oxide inclusions located in the a-Si:H matrix. Indeed, the Mössbauer spectroscopy method demonstrates that the a-Si:H(Er) films fabricated by the MASD technique contain [Er–O] clusters, in which the

Er^{3+} ions have the local surrounding similar to Er_2O_3 [9]. Additionally, it was shown in Ref. [10], that Er_2O_3 with excess of oxygen (that is similar to our case) has to contain the interstitial O^- ions and holes located at Er^{3+} ions. The hole and O^- ion represent a dipole, which can shift its position in the applied external electric field. Thus, we supposed that, in the [Er–O] clusters, the thermally polarized processes with activation energies from 0.85 to 1.00 eV can be connected to dipole polarization of the hole– O^- dipoles.

The hole trapping in the a-Si:H(Er) film at reverse bias of the a-Si:H(Er)/c-n-Si diode is in contradiction with the model of electroluminescence in such structure, which was suggested in Ref. [5]. In this regime of heterodiode operation, this model assumes that electrons are injected from Al electrode into the a-Si:H(Er) film followed by trapping at dangling bonds (D^0 -centers) and energy transfer (about 0.8 eV) to Er^{3+} ions, located near D^0 -centers. In this model, hole trapping was neglected. Our experiments demonstrate that in the considered devices, the applied reverse bias leads to effective hole trapping in the traps with deep levels

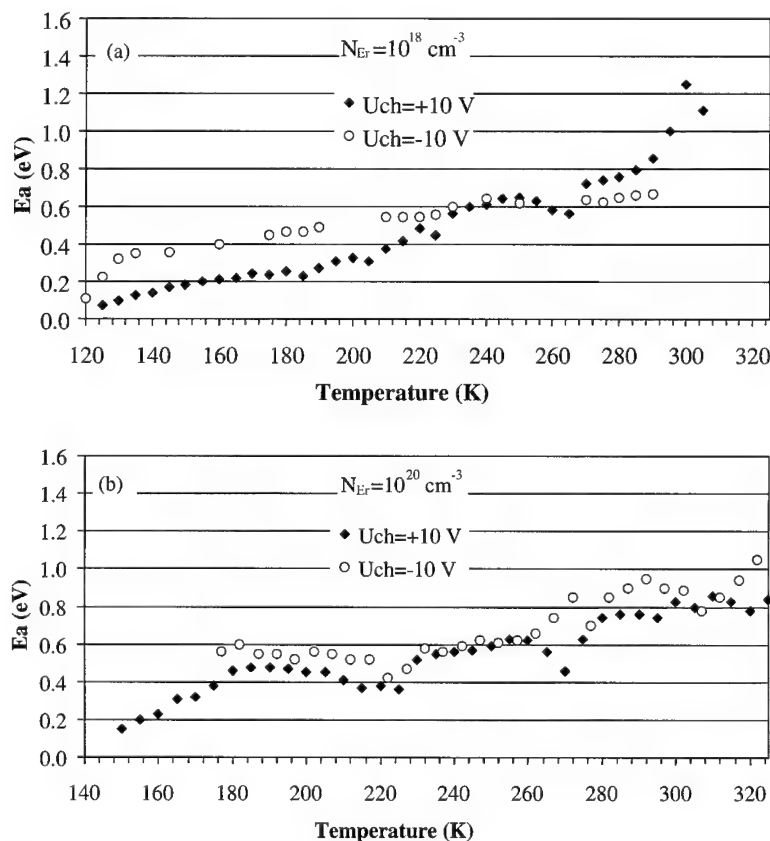

Fig. 3. Results of fractional thermal cleaning of the TAC spectra, measured on the MASD heterodiode with the a-Si:H(Er) film, doped by Er with concentrations of 1×10^{18} (a) and $1 \times 10^{20} \text{ cm}^{-3}$ (b).

Fig. 4. Proposed model of resonance energy transfer from A–D pair, localized in $E_c - 0.50$ eV level and $E_v + 0.50$ eV level, to Er^{3+} in a-Si:H material.

$E_v + 0.50$ eV and, probably, has to be taken into account for the model of electroluminescence.

It should be noted that electron and hole traps are spatially correlated because of their location links with [Er–O] cluster location. Electron trapping at the levels $E_c - 0.55$ or 0.60 eV and hole trapping at the level $E_v + 0.50$ eV result in creation of donor–acceptor (D–A) pair located in vicinity of the [Er–O] cluster. The energy of the D–A annihilation is about 0.8 – 0.9 eV, which corresponds to the energy of resonance excitation (0.84 eV) of electron in Er^{3+} ion from the ground state $^4I_{15/2}$ to the $^4I_{13/2}$ state (Fig. 4). Since the Er–O bond

exhibits ionic properties, it can be considered as an $\text{Er}^{3+} - \text{O}^-$ dipole. Thus, the D–A pair created can interact with the Er–O bond by dipole–dipole interaction and during its annihilation to transfer the energy to Er by the dipole-mediated energy transfer [11], proposed by Förster for excitation transfer between molecules in gases or solutions and used in Ref. [12] for the a-Si:H(Er) material, in order to explain the energy transfer between dangling bonds and Er^{3+} ions located at sufficiently long distances (nearly 100 Å) from one another.

Spectroscopic characterisation of the erbium impurity in crystalline semiconductors

C.A.J. Ammerlaan*

Van der Waals-Zeeman Institute, University of Amsterdam, Valckenierstraat 65, 1018 XE Amsterdam, Netherlands

Abstract

A scheme for the numerical calculation of energy levels of rare-earth ions in a crystalline solid is presented. Stark fields of cubic, trigonal, tetragonal, orthorhombic and monoclinic symmetry are considered. As examples, optical luminescence spectra of erbium in the semiconductors zinc selenide and silicon are analysed. Based on the optical characterisation, the g tensors for Zeeman splitting in an applied magnetic field are predicted for the crystal-field ground states of these centres. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Spectroscopy; Erbium; Zinc selenide; Silicon

1. Introduction

Spectroscopy is a general powerful tool for the investigation of electronic and atomic structure of matter, including solids and electronic centres in solids related to defects or impurities. By spectroscopy, transition energies and probabilities, parameters which are directly linked to the description of materials in fundamental terms of quantum mechanics are measured. Modern spectrometers, with high sensitivity and energy resolution, are capable of providing an abundance of very precise experimental data. In order to have the full profit of measured data, the interpretation in terms of solutions of the eigenvalue equations must be given. Unfortunately, often the system description is very complex due to, e.g., low symmetry or high spin. In general, an exact analytical solution of equations is only possible in specific cases of high symmetry. Applying perturbation theory, the range of analytical solutions can be extended, but perturbation methods suffer from limited applicability and unsatisfactory accuracy as well. To circumvent these strong limitations, the alternative method of numerical solution can be applied. This paper

describes a scheme for the calculation of energy levels, and at the same time wave functions, of rare-earth impurities in crystalline solids. The method is outlined and illustrated by the examples of the erbium ion in the semiconductor crystals zinc selenide and silicon, with the zincblende and diamond structures, respectively. The ground state of the Er^{3+} ion with electronic configuration $4f^{11}$ and, hence, orbital momentum $L = 6$ and spin $S = \frac{3}{2}$, is formed by spin-orbit interaction as a $^4I_{15/2}$ level. Calculations on this state are performed in the effective spin $J = \frac{15}{2}$ formalism. When included in a solid, the 16-fold degeneracy of the atomic state is partially lifted by crystal fields of ligand atoms of the host crystal with the formation of quartet and doublet levels. Application of a magnetic field, also considered in this paper, will result in 16 non-degenerate states.

2. Crystal-field Hamiltonian

In several cases, the erbium ion occupies a site of high symmetry, e.g. an undistorted substitutional site or interstitial T site. For rare-earth ions with $4f$ orbitals the only non-vanishing matrix elements are due to fourth- and sixth-order crystal-field operators. On the basis of a point-charge model, expressions for the potential are

Table 1
Potentials representing the eight systems in the diamond crystal structure^a

System	Potential					
	x^2	y^2	z^2	xy	yz	zx
Cubic	—	—	—	—	—	—
Trigonal	—	—	—	δ	δ	δ
Tetragonal	—	—	γ	—	—	—
Orthorhombic-I	—	—	γ	δ	—	—
Monoclinic-I	—	—	γ	δ	ϵ	ϵ
Orthorhombic-II	—	β	γ	—	—	—
Monoclinic-II	—	β	γ	δ	—	—
Triclinic	—	β	γ	δ	ϵ	ζ

^a Normalised second-order operators are constructed in a way as demonstrated by Eq. (5).

derived as

$$V_4 = 35(x^4 + y^4 + z^4) - 21r^4 \quad (1)$$

and

$$V_6 = 231(x^6 + y^6 + z^6) - 315(x^4 + y^4 + z^4)r^2 + 90r^6. \quad (2)$$

Following the rules of quantum mechanics, the potentials are transformed into effective crystal-field operators. These are the familiar expressions $H_{cu4} = O_4^0 + 5O_4^4$ and $H_{cu6} = O_6^0 - 21O_6^4$. In case of lower

symmetry, additional operators are required. For the diamond and related crystal structures eight different systems can be distinguished, ranging from high-symmetry cubic, via axial trigonal and tetragonal, towards orthorhombic and monoclinic, to the lowest-symmetry case of the triclinic system. Associated crystal-field potentials represented by their leading second-order term are listed in Table 1. Again, the expressions for potential are transformed into operators by forming symmetrised forms of corresponding operators. From these operators, the matrix elements are formed in the basis set of the 16 spin states $|15/2, m_J\rangle$ of the erbium ion.

The more general expression as used in the analyses of cases to be presented is of the monoclinic-I form. It is given by

$$H_{cf} = V_{cf}(\cos \eta H_{cu} + \sin \eta H_{mo}) \quad (3)$$

with

$$H_{cu} = \sin \alpha H_{cu4} + \cos \alpha H_{cu6} \quad (4)$$

and

$$H_{mo} = \cos \gamma H_{zz} + \sin \gamma [\cos \delta H_{xy} + (1/2)\sqrt{2} \sin \delta (H_{yz} + H_{zx})]. \quad (5)$$

The usual scaling factors, $F(4) = 60$, $F(6) = 13860$, etc. are included in the operator expressions. Parameters η ,

(a) calculated levels in cubic symmetry with parameters $V_{cf} = 0.323$, $\alpha = -0.7^\circ$, (b) averaged to five-line spectrum, and (d) calculated levels in monoclinic-I symmetry, parameters $V_{cf} = 0.334$, $\eta = 26.3^\circ$, $\alpha = -2.7^\circ$, $\gamma = 37.0^\circ$, $\delta = 33.1^\circ$.

Fig. 2. Crystal-field energy levels in state $^4I_{15/2}$ of the Si-Er-I centre. (c) Eight levels derived from the photoluminescence spectrum. (a) calculated levels in cubic symmetry with parameters $V_{cf} = 0.430$, $\alpha = -1.7^\circ$, (b) averaged to five-line spectrum, and (d) calculated levels in orthorhombic-I symmetry, parameters $V_{cf} = 0.437$, $\eta = 19.3^\circ$, $\alpha = -2.0^\circ$, $\gamma = 24.8^\circ$, $\delta = 0^\circ$.

Fig. 3. Crystal-field energy levels E in state $^4I_{15/2}$ of the non-cubic ZnSe:Er $^{3+}$ centre as a function of parameter η of tetragonal distortion, $V_{cf} = 0.323$, $\alpha = -0.7^\circ$. Data points in averaged cubic symmetry are shown at $\eta = 0^\circ$. Best match to potential with tetragonal symmetry is at $\eta = 19.7^\circ$.

Fig. 4. Crystal-field energy levels E in state $^4I_{15/2}$ of the non-cubic centre Si-Er-1 as a function of parameter η of tetragonal distortion, $V_{cf} = 0.430$, $\alpha = -1.7^\circ$. Data points in averaged cubic symmetry are shown at $\eta = 0^\circ$. Best match to potential with tetragonal symmetry is at $\eta = 16.4^\circ$.

α , γ and δ , in the range $-90^\circ \leq \eta, \alpha, \gamma, \delta \leq +90^\circ$, decide upon the form of the potential, the strength is given by factor V_{cf} . Energy eigenvalues, together with coefficients of wave functions, are obtained by diagonalisation of the 16×16 matrices.

3. Zeeman-effect Hamiltonian

By adding the energy of the Zeeman effect, the splitting of energy levels in a magnetic field $B(B_x, B_y, B_z)$ can be calculated. The relevant Hamiltonian

$$H_{mf} = g_J \mu_B (B_x J_x + B_y J_y + B_z J_z) \quad (6)$$

does not introduce any new free adjustable parameters. For the ground state $^4I_{15/2}$ of erbium, the Landé factor $g_J = \frac{6}{5}$.

4. Luminescence spectra

Well-identified eight-line photoluminescence emission spectra are observed, among other substances, in zinc selenide and silicon [1,2]. From these spectra, the positions of the crystal-field states in the $^4I_{15/2}$ spin-orbit ground state are constructed. An inspection of the level diagrams, as given in Figs. 1(c) and 2(c), suggests

the presence of pairs of lines, which find their origin in a relatively small splitting of quartet levels in centres of near-cubic symmetry. On averaging the positions of line pairs, an analysis in cubic symmetry can be made [1]. The result is included in Figs. 1 and 2 in columns (a) and (b), and in Figs. 3 and 4 by the data points for $\eta = 0$. It can be concluded that satisfactory fits can be made. Also, with nearly equal values for the cubic field parameter α , the two spectra show a strong similarity.

Actually, the eight-line spectra belong to centres of lower-than-cubic symmetry. The splitting of quartet levels in an axial field of tetragonal symmetry is shown in Figs. 3 and 4, including experimental level positions at the best adjusted value of parameter η , governing the balance of cubic and tetragonal potentials. To obtain best match of the calculated level positions, least squares adjustments were made to the experimental data of both spectra. Parameter sets are summarised in Figs. 1 and 2. For the ZnSe centre a monoclinic-I potential was found to give best agreement. The Si-Er-1 centre was fitted with orthorhombic-I symmetry; adding any monoclinic-I component deteriorated the result. Typical root-mean-square errors are around 4 cm^{-1} , therefore larger than the estimated experimental errors of around 1 cm^{-1} .

5. Magnetic resonance spectra

With potential parameters determined from the optical spectra, the splitting of doublet levels in a magnetic field can be calculated in a straightforward manner with the Hamiltonian H_{mf} (Eq. (6)). Calculations were restricted to the regime of low magnetic field, in which the Zeeman effect is proportional to the magnetic field and, hence, the g tensors are constant. For centre $ZnSe:Er^{3+}$, the monoclinic-I symmetry is in agreement with the reported spectrum [1]. However, the calculated principal values $g_1 = 11.96$, $g_2 = 2.45$ and $g_3 = 4.86$ deviate substantially from values of the magnetic resonance spectrum labelled A. The identification of optical and EPR centres is thus not supported. For centre Si–Er-I, the calculated principal g values are $g_{[0,0,1]} = 3.33$, $g_{[1,1,0]} = 6.09$ and $g_{[1,-1,0]} = 10.27$. Evidently, the g tensor of an

orthorhombic Si–Er-I centre in silicon cannot be identified with the monoclinic-I EPR spectrum Si–OEr-I reported recently [3]. In view of different production conditions of the erbium optical centres the result is not surprising.

Ultra-fast diffusion mechanism of the late 3d transition metal impurities in silicon

Y. Kamon, H. Harima, A. Yanase, H. Katayama-Yoshida*

Department of Condensed Matter Physics, The Institute of Scientific and Industrial Research, Osaka University, Osaka 567-0047, Japan

Abstract

Based upon *ab initio* electronic structure calculations with super-cells and an FLAPW method, we discuss the mechanism of the ultra-fast diffusion and the reduction of the migration barriers of the late 3d transition atom impurities of Co, Ni and Cu in silicon. The reduction mechanism of the migration barriers of the late 3d transition metal impurities is due to the pseudo-Jahn-Teller interaction, in which the six-fold-coordinated bonds are formed at the interstitial D_{3d} symmetry site and the energy gain by these bonds overcomes that of the four-fold-coordinated bonds at the tetrahedral T_d interstitial site. For Sc, Ti, V, Cr, Mn and Fe impurities in silicon, the T_d interstitial site is more stable than the D_{3d} site, however, for Co, Ni and Cu impurities, the D_{3d} interstitial site becomes more stable than the T_d interstitial site. Calculated migration barriers are in reasonably good agreement with the experimental data. We discuss the systematic variation of the chemical trend of the migration barrier of 3d transition metal impurities in silicon based upon the calculation. © 2001 Elsevier Science B.V. 1. Introduction

The 3d transition metal impurities of Sc, Ti, V, Cr, Mn, Fe, Co, Ni and Cu (hereafter called 3d TM) in silicon show the large variation in the chemical trend of the diffusion coefficients up to 6 orders of magnitude in the difference within the 3d TM series [1]. Late 3d TM impurities in silicon, such as Co, Ni and Cu, diffuse ultra-fast and the measured diffusion coefficients are larger than that of Li or H. However, early 3d TM impurities, such as Sc, Ti, V and Cr, diffuse very slowly and the diffusion coefficient reduces almost 6 orders of magnitude compared with the late 3d TM impurities. For a long time, it has been believed that the large differences and chemical trend in the diffusion coefficient of 3d TM series in silicon is due to the difference of the

atomic size between the early 3d TM (large atomic size) and the late 3d TM (small atomic size). Diffusion coefficient (D) is given by $D = D_0 \exp(-\Delta E/k_B T)$, where ΔE is the migration barriers of the diffusion. Since the experimentally observed pre-factor D_0 of diffusion coefficient is approximately the same value for all the 3d TM impurities in silicon (see the data in Ref. [1]), the large chemical trend in the difference of D originates mainly from the difference of the diffusion barrier (ΔE) in the experiment. The experimental value ΔE changes one order from Sc (3.2 eV [1]), Ti (1.5–2.05 eV [1]), V (1.55–2.8 eV [1]), Cr (0.79–1.1 eV [1]), Mn (0.63–1.3 eV [1]), Fe (0.43–1.1 eV [1]), Co (0.37 eV [1]), Ni (0.13–0.76 eV [1]) to Cu (0.18–0.86 eV [1]) within the error bars depending on the various experimental methods. The mechanism of the large chemical trend in the observed ΔE should be ascribed to the electronic origin because the difference of the ΔE between the early 3d TM and the late 3d TM impurities in silicon is almost one order. So far, there is no *ab initio* electronic structure calculation to study the origin of the migration barriers

(H. Katayama-Yoshida).

in the diffusion and the large chemical trend of the diffusion coefficients of 3d TM impurities in silicon.

Based upon the total energy calculation using *ab initio* electronic structure calculation by the FLAPW with super-cell method, we calculate the systematic variation of the migration barrier of the diffusion for 3d TM impurities of Sc, Ti, V, Cr, Mn, Fe, Co, Ni and Cu in silicon. We give the calculation method in Section 2. We discuss the principal mechanism of the reduction of the migration barrier of the late 3d TM impurities based upon the pseudo Jahn-Teller mechanism in Section 3. In Section 4, we give the calculated results and discussion. Summary is devoted in Section 5.

2. Calculation method

We used a full potential linearized augmented plane wave (FLAPW) method within the local density approximation (LDA) with the super-cells containing sixteen silicon atoms and one 3d TM. We assumed the non-magnetic state for the calculation of the migration barrier of 3d TM because most of the measurement of diffusion coefficient is done at high temperatures up to 1200°C. Here, solubility of Cu is about 10^{18} cm^{-3} at 1200°C and 10^{11} cm^{-3} at room temperature. It is well known from the EPR measurement that the isolated V, Cr, Mn and Fe impurities are located at the tetrahedral (T_d) interstitial site in silicon at low temperatures [2]. We have no available EPR data for Co, Ni and Cu impurities in silicon. Since these late 3d TM impurities diffuse very fast even at the low temperature, then it was very difficult to observe the EPR signals. We took into account the interstitial diffusion mechanism of 3d TM impurities in silicon and calculated the migration barrier through the interstitial diffusion mechanism. We did not take into account the kick-out mechanism or direct exchange mechanism of diffusion for 3d TM impurities in silicon. We have calculated migration barriers from the tetrahedral T_d interstitial site to the next nearest T_d site through the D_{3d} (the center of six-atom rings of the silicon, see Fig. 1). Total energy is calculated for seven positions of 3d TM on the straight lines between two T_d interstitial sites. The center of the nearest two T_d interstitial sites is the D_{3d} site. Since the large atomic radii of 3d TM at the interstitial site may bring a large lattice relaxation, we have taken into account the lattice relaxation in which we relaxed the first neighbor silicon with keeping its local symmetry. We used the Γ point for the total energy calculation in our super-cells. We expand the spherical harmonics up to $l = 7$ in each muffin-tin sphere ($r = 0.0991a$, where a is the lattice constant and $a = 10.86 \text{ \AA}$).

Fig. 1. Interstitial diffusion model through the path $T_d \rightarrow D_{3d} \rightarrow T_d$. For the total energy calculation, we take into account the lattice relaxation of first nearest neighbor silicon atoms.

3. Reduction mechanism of the migration barrier by pseudo-Jahn-Teller interaction

The general theory of the bi-stability of impurities in covalent semiconductors is given by a pseudo-Jahn-Teller interaction [3,4]. The ground state energy $E_0(Q)$ can be expanded by atomic displacement Q (see Fig. 2a),

$$E_0(Q) = E_0(0) + \frac{1}{2}(K_s + K_v)Q^2 + O(Q^4) + \dots \quad (1)$$

Here $K_s > 0$ is the static (s) elastic force constant, and $K_v < 0$ represent the charge relaxation due to the displacement-induced vibronic (v) coupling between the ground states $|0\rangle$ and excited states $|i\rangle$,

$$K_v = -2 \sum_{i \neq 0} \frac{|\langle 0 | \delta H / \delta Q | i \rangle|^2}{(E_i - E_0)}. \quad (2)$$

Pseudo-Jahn-Teller distortions ($K_s + K_v < 0$) are possible when the vibronic coupling competes favorably with static force constant (see Fig. 2b). Eqs. (1) and (2) suggest that one should search for structural instabilities in (i) intrinsically "soft" semiconductors (small K_s) such as amorphous semiconductors or semiconductor surface, and (ii) impurities with low-lying excited states that couple strongly to the ground state through displacement ($|K_v|$ large) such as the element with p-s coupling ($\langle 0 | = p$, $\langle i | = s$) in the second period of the periodic table or IIB-VI (IB-VII) semiconductors with d-s coupling ($\langle 0 | = d$, $\langle i | = s$) containing transition atoms [3].

Hydrogenated amorphous silicon (a-Si:H) is intrinsic soft (small K_s), therefore we have found a structural instability (bi-stability) $K_s + K_v < 0$ with p-s coupling between the states near the valence band maximum

(generally made up of atomic p-orbital) and the states near the conduction band minimum (generally s-orbitals) [5,6]. The impurity atoms of the second period of the periodic table, such as substitution nitrogen impurity in crystalline diamond (c-C:N), are also a candidate for the structural instabilities because p-s coupling between 2p- and 2s-orbital in nitrogen atom is very large (large $|K_v|$) with similar spatial distribution of 2p- and 2s-orbitals [7,8].

For the late 3d TM impurities such as Co, Ni and Cu in silicon, the impurity 3d states (e_g -states) in the band gap can couple strongly with the low-lying excited states of the conduction band (4s-orbital) due to the strong d-s coupling in the pseudo-Jahn-Teller interaction. In the case of Cu impurity in silicon, the excitation energy from $3d^{10}4s^1$ to $3d^94s^2$ is very small compared with that of the early 3d TM such as Ti from $3d^34s^1$ to $3d^24s^2$. Then we can expect the structural instability for the late 3d TM impurities such as Co, Ni and Cu in silicon, in which T_d site becomes unstable due to the bi-stability and 3d TM impurity migrates from the T_d site to the more stable lower symmetry D_{3d} site by reducing the migration barrier. In this case we expect the reduction of the migration barrier with forming the bi-stability and the re-bonding from T_d site to D_{3d} site with forming another bond due to the strong d-s coupling in the pseudo-Jahn-Teller effect.

4. Calculated results and discussion

It is well known that the most of the 3d TM impurities in silicon are located at the tetrahedral interstitial site (T_d) by EPR experiments [2]. Very small Jahn-Teller distortions are observed due to the strong covalency relative to the ionicity in 3d TM impurities in silicon at the T_d site. Due to the p-d hybridization between the impurity 3d orbital and host p orbital at the T_d interstitial site, it forms a bonding state in the valence band and the anti-bonding counterpart is pushed up into the band gap. Since the p-d hybridization between the $3d\gamma$ [$3z^2-r^2$, x^2-y^2] orbitals and p orbitals [p_x, p_y, p_z] of the octahedrally coordinated second nearest neighbors is larger than the hybridization between the $3de$ [xy, yz, zx] orbitals and p orbitals [p_x, p_y, p_z] of the tetrahedrally coordinated first nearest neighbors, three degenerate t_{2g} -states are located below the two degenerate anti-bonding e_g -states [9,10]. The energy difference between the e_g - and t_{2g} -states is called the crystal field splitting (Δ_{CF}). If the exchange splitting (Δ_{EX}), the energy difference between the up spin and down spin states, is larger than the Δ_{CF} , high-spin state is realized [11]. Otherwise, the low-spin state is realized. Here, we did not take into account the spin-polarization because the diffusion experiment was done at high temperatures up to 1200°C.

Table 1 shows the stable atomic site and the calculated migration barriers with lattice relaxation and without lattice relaxation compared with the available experimental data. The large ionic radii of the early 3d TM impurities such as Sc, Ti, and V show the large lattice relaxation, however, the late 3d TM impurities such as Fe, Co, Ni and Cu show the small lattice relaxation (see Table 1). We found that the most stable atomic position of the Sc, Ti, V, Cr, Mn and Fe impurities in silicon is the T_d site, a maximum of the migration barrier is located at the D_{3d} site (the center site of the two connected T_d sites, and the center of six-fold-coordinated rings of silicon atoms in Fig. 1). On the other hand, the D_{3d} site becomes more stable for the late 3d TM impurities of Co, Ni and Cu in silicon. We show the adiabatic potential surface of Cu impurity in silicon through the migration path $T_d \rightarrow D_{3d} \rightarrow T_d$

Fig. 2. Schematic explanation of the existence of bi-stability due to a pseudo-Jahn-Teller interaction. (a) Single local minimum, and (b) bi-stability of impurity site.

Table 1

Experimentally observed migration barriers [1], calculated migration barriers without lattice relaxation, calculated migration barriers with lattice relaxation of 3d transition metal impurities in silicon. The most stable atomic site of the impurity is indicated in the table

3d TM element	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu
Experiment (eV)	3.20	1.5–2.05	1.55–2.8	0.79–1.1	0.63–1.3	0.43–1.1	0.37	0.13–0.76	0.18–0.86
Calculation without lattice relaxation (eV)	5.48	4.97	3.96	2.78	1.74	0.95	0.49	0.75	0.35
Calculation with lattice relaxation (eV)	3.80	3.76	3.06	2.07	1.17	0.30	0.25	0.31	0.35
Most stable atomic site	T_d	T_d	T_d	T_d	T_d	T_d	D_{3d}	D_{3d}	D_{3d}

(see Fig. 3). The mechanism of the stability at the lower symmetry D_{3d} site of Co, Ni and Cu is due to the pseudo-Jahn-Teller interaction, as was discussed in Section 3, which is caused through the excitation from the $3d^n 4s^0$ to $3d^{n-1} 4s^1$. We compare the charge density of Cu impurity at the T_d site in $(1\bar{1}0)$ plane and the D_{3d} site in $(1\bar{1}0)$ plane (see Fig. 4). A weak

Fig. 3. Adiabatic potential surface of Cu impurities in silicon through the path $T_d \rightarrow D_{3d} \rightarrow T_d$. The position of Cu impurity's position is $(X, Y, Z) = (a, a, a)$ in the super-cell.

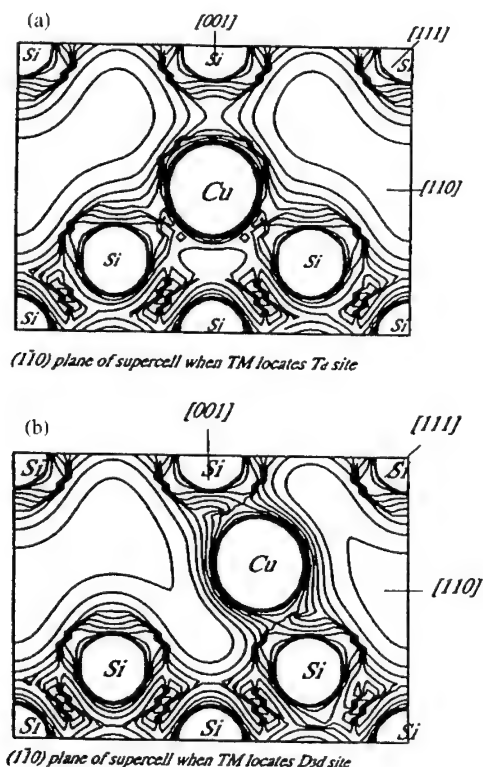

Fig. 4. Calculated the charge density of Cu impurity (a) at the T_d site in $(1\bar{1}0)$ plane and (b) the D_{3d} site in $(1\bar{1}0)$ plane.

bond between the anti-bonding state (conduction band) of silicon and Cu-4s state are formed at the D_{3d} site with stabilizing the bond. Since the coordination number of six at the D_{3d} site is larger than that of four at the T_d site, the energy gain at the D_{3d} site due to the pseudo-Jahn-Teller interaction overcomes that of at the T_d site. We can confirm this stability mechanism in the Cu-4s partial density of states in Fig. 5, in which the Cu-4s state are occupied below the Fermi level (E_F) with forming a bond between the Si anti-bonding state and the Cu 4s states (see Fig. 4). We calculate the diffusion

Fig. 5. Calculated (a) total density of states of host silicon in the super-cell, (b) total density of states of Cu at the D_{3d} site, (c) Cu-4s partial density of states at the D_{3d} site, where Cu-4s state are occupied below the Fermi level (E_F) with forming a bond between the Si anti-bonding state and the Cu-4s states, and (d) Ni-4s partial density of states at the D_{3d} site.

barriers using the adiabatic potential surfaces of the 3d TM impurities in silicon through the paths $T_d \rightarrow D_{3d} \rightarrow T_d$ and $D_{3d} \rightarrow T_d \rightarrow D_{3d}$ sites (see Fig. 2). Calculated diffusion barriers are in good agreement with the experimental data within the experimental error bars.

The development of the control method for the ultra-fast diffusion of Cu becomes very important from the technological point of view, because recently a Cu-wire bonding in silicon devices to reduce the contact resistivity has also become very important in silicon device technology where the migrated interstitial Cu impurity works deep in the impurity levels and acts as a carrier killer. In order to develop the impurity-gettering technology of Cu impurities in silicon, we should understand the mechanism of the ultra-fast diffusion of Cu. Then, we can speculate and design a new impurity-gettering technology of Cu impurity in silicon based upon the calculation.

5. Summary

We discuss the chemical trend of the migration barrier and the electronic structure of 3d transition metal impurities in silicon by *ab initio* electronic structure calculations with super-cells and FLAPW method. We calculate the electronic structure and migration barrier of diffusion of 3d TM impurities in silicon. We propose the mechanism of the ultra-fast diffusion and the reduction mechanism of the migration barriers of the late 3d transition atom impurities of Co, Ni and Cu in silicon. The reduction mechanism of the migration barriers of the late 3d transition metal impurities such as Co, Ni and Cu is due to the pseudo-Jahn-Teller interaction, in which the six-fold-coordinated bonds are formed at the lower D_{3d} symmetry at the interstitial site and the energy gain by these bonds overcomes that of the four-fold-coordinated bonds at the tetrahedral T_d interstitial site. For Sc, Ti, V, Cr, Mn and Fe, the T_d interstitial site is more stable than the D_{3d} site, however, for Co, Ni and Cu, the D_{3d} interstitial site becomes more

stable than the T_d interstitial site. Calculated migration barriers are in good agreement with the available experimental data.

Abstract

Gold diffusion in Czochralski grown (Cz) Si with and without nitrogen, introduced during growth, has been studied. It is found that the Au concentration in substitutional positions after diffusion at 700°C, 750°C and 800°C in Cz Si doped with nitrogen is always less than that in usual Cz Si. A decrease of the substitutional Au concentration in nitrogen doped crystals can be explained under the assumptions that nitrogen or nitrogen-related centers stimulates oxygen precipitation and suppresses the grown-in defect formation. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Nitrogen; Silicon; Gold diffusion; Self-interstitials

1. Introduction

Gold and platinum diffusion is now widely used for studying the defect distribution in crystalline silicon [1–7]. These impurities are known to diffuse at high temperatures via the kick-out mechanism [8]. That means that gold can diffuse very quickly over interstitial sites Au_i and then Au_i are transformed into electrically active substitution sites Au_s via the kick-out reaction

This reaction is accompanied by self-interstitial *I* generation and the excess self-interstitials should be annihilated at sinks: the surface in defect-free silicon or additionally on bulk defects. Therefore, the *I* concentration and, in turn, the Au_s distribution is sensitive to the change of the self-interstitial generation or annihilation rates. So, the defects playing a role of effective sinks for self-interstitial atoms could lead to an essential increase in the Au_s concentration. Such an increase was observed in dislocated [1] or ion-implanted [4–6] silicon and in silicon containing

grown-in vacancy type defects [3]. On the other hand, a decrease in the Au_s concentration is usually associated with an enhanced self-interstitial generation that could lead to a reversion of the kick-out reaction. An essential decrease in the Au_s concentration was observed [2] after gold diffusion in Czochralski (Cz) grown silicon samples, in which the effective nucleation sites for oxygen precipitation were generated by preliminary annealing, and in Si with H- and He-implantation induced nanocavities [7].

Nitrogen is known to affect many of silicon properties [9]. Thus, it locks dislocations, increasing the Si wafer mechanical strength [10,11] and suppresses the creation of oxygen-related thermal donors [12,13]. Recently it was found that nitrogen can enhance the nucleation of oxygen precipitation [14] and suppress void defects aggregated by vacancies [15]. The nitrogen solubility limit in Si is rather small (about 10¹⁵ cm⁻³); usually it is present in silicon in an electrically inactive state, only a small part of the nitrogen interacting with oxygen produces shallow donors [16,17]. Therefore, only a limited number of characterization techniques can be used to reveal the nitrogen-related defects that study their effect on Si properties. One of such methods could be associated with a study of nitrogen effect on the generation and annihilation of intrinsic point defects by investigations of gold diffusion. The sensitivity of gold diffusion to grown-in defects increases with decreasing

diffusion temperature. Oxygen precipitation leading to self-interstitial generation also depends on the annealing temperature. Therefore, to separate the effect of both processes the gold diffusion should be carried out in a rather wide temperature range.

In the present paper a comparative study of the Au_s concentration in n-type Si grown by the Czochralski (Cz) method in an argon or nitrogen atmosphere after diffusion annealing in the temperature range from 700°C to 800°C, has been carried out. It is shown that in nitrogen containing crystals the Au_s concentration is lower than that in Si grown in an argon atmosphere. The results obtained are explained taking into account the nitrogen-related stimulation of oxygen precipitation and the suppression of vacancy type grown-in defect formation.

2. Experimental

Cz Si wafers of n-type conductivity with a thickness of 300 μm doped with phosphorus to a concentration of about 10^{14} cm^{-3} were used in our experiments. Nitrogen doped Si ingots (NCz) were grown in a nitrogen atmosphere while the Cz ingots without nitrogen were grown in similar conditions but in an argon atmosphere. Pairs of Cz and NCz Si wafers cut from almost the same tail or head parts of ingots, which contain very similar oxygen concentrations of about $1.0 \times 10^{18} \text{ cm}^{-3}$ and similar phosphorus concentrations, were compared. The oxygen and carbon concentrations in the samples were measured by IR absorption at room temperature using the calibration factors $3.14 \times 10^{17} \text{ cm}^{-2}$ for oxygen and $1.0 \times 10^{17} \text{ cm}^{-2}$ for carbon, respectively. The carbon concentration was less than $5 \times 10^{15} \text{ cm}^{-3}$. All samples studied were subjected to annealing at 650°C for 30 min after growth to anneal oxygen-related thermal donors. In the NCz samples nitrogen–oxygen shallow donors are formed under such annealing [16,17]. On one side of the samples, gold films with a thickness of about 30 nm were evaporated. Then gold diffusion annealing was carried out at 700°C, 750°C or 800°C for 1 h in air. After diffusion annealing a layer of about 50 μm thickness was removed by mechanical polishing from one side of all gold diffused samples. Then the samples were chemically etched for removing the damaged layer, and Schottky barriers were formed on the polished surface by thermal evaporation of Au. Ohmic contacts were produced by scratching the back side of the samples with the eutectic InGa alloy. The Au_s concentration and its depth profile were measured by deep level transient spectroscopy (DLTS). The total Au_s concentration was calculated as a sum of the concentrations of centers with the deep levels $E_c - 0.54 \text{ eV}$ and $E_c - 0.20 \text{ eV}$, associated with Au_s and gold–hydrogen complexes formed under chemical etching [18,19], respectively.

3. Results and discussion

First of all it should be mentioned that, as an extrapolation of high temperature data [1,20,21] shows (Fig. 1), after 1 h diffusion the Au_s concentration in the middle of the wafer at diffusion temperatures below 840°C should be lower than that of the Au_i solubility limit. Therefore the question arises if the resulting Au_s concentration is determined by the kick-out reaction at the diffusion temperatures used in the present study. To check this point the gold profile in Cz Si after 700°C diffusion was measured. It is seen (Fig. 2) that even in this samples, which demonstrates the deviation of Au_s concentration from that in defect-free Si (see below), the profile measured correlates well with that predicted by the kick-out mechanism. Besides, the measured Au_s concentrations correlate rather well with those predicted by the extrapolation of the high temperature data (Fig. 3). In this figure the results obtained on the

Fig. 1. Au_s concentration in the middle of the wafer after 1 h diffusion obtained by extrapolation from the high temperature experiments [1,20,21]. The solubility limits for Au_i and Au_s^* , calculated using the dependences presented in Ref. [21] are shown by dotted lines.

Fig. 2. Au_s profiles measured in Cz silicon after 700°C diffusion (points) and predicted by the kick-out mechanism (solid line).

Fig. 3. Au_s concentrations measured by the DLTS in Cz and NCz silicon (head part of ingots) after diffusion annealing at 700°C, 750°C, and 800°C for 1 h. The predicted Au_s concentrations at the depth of 50 μm and in the middle of sample are shown by the solid and dotted lines, respectively.

samples cut from the head part of the ingots are presented. On the samples cut from the tail part of the ingots the results are practically the same.

It is seen that at all diffusion temperatures used, the Au_s concentration in NCz samples is lower than that in the corresponding Cz samples and the difference between the two types of crystals increases with decreasing diffusion temperature. The calculated Au_s concentrations in defect-free Si at a depth of 50 μm and in the middle of the wafer are also presented in Fig. 3. The first values are obtained by multiplying the last ones by 1.6 (the coefficient obtained from the kick-out profile). It is seen that the Au_s concentration in Cz samples after 750°C and 800°C diffusion is close to that in defect-free Si but after 700°C diffusion it is about three times larger. This could be explained assuming that some vacancy type grown-in defects are present in the Cz samples. At low diffusion temperatures these defects can play the role of sinks for self-interstitials that leads to the Au_s concentration increase. The increase of diffusion temperature leads to an increase of self-interstitial generation rate that can lead to the disappearance or reconstruction of these grown-in defects.

The Au_s concentration in NCz samples at all temperatures used is lower than that predicted for defect-free Si. This decrease can be explained as the result of an enhanced oxygen precipitation in such crystals that was already observed in Ref. [13]. Self-interstitials generated under oxygen precipitation can reverse the kick-out reaction and decrease the Au_s concentration. No effect of grown-in defects on the Au_s concentration was observed in NCz Si after 700°C diffusion. This could mean that the oxygen precipitation effect masks that of the grown-in defects or, more

probably, that nitrogen suppresses the formation of such defects.

4. Conclusion

Thus, the decrease of the Au_s concentration in NCz samples as compared with that in Cz samples after gold diffusion in the temperature range from 700°C to 800°C is observed. The difference is found to increase with decreasing of diffusion temperature. The results obtained can be explained by the effect of nitrogen on the grown-in defect formation and/or by the nitrogen-related enhancement of oxygen precipitation.

New electron spin resonance spectra from iron–vacancy pair in silicon: II. Hyperfine interactions and isotopic effect

T. Mchedlidze*, M. Suezawa

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan

Abstract

We studied the TU2 and TU3 ESR spectra from an iron–vacancy pair in iron-doped and electron-irradiated float-zone grown silicon samples. Isotopic shifts in the fine structure term and hyperfine and superhyperfine interaction terms of the spin Hamiltonian are considered in detail. We obtained that the change in the spin value of the defect is accompanied by a modification of the iron atom position. The existing model fails to explain observed large anisotropy of the isotopic effect. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Fe; Vacancy; ESR

1. Introduction

The presence of isotopic shifts in the ZFS (fine structure) term of the spin Hamiltonian of newly observed spectra from the iron–vacancy pair in Si requires simultaneous treatment of terms related to hyperfine (HF) and superhyperfine (SHF) splitting and the isotopic shift. A quantitative model of the isotopic shifts in the ESR spectra has not yet been developed. Qualitatively, the effect can be considered in terms of the theory for localized vibrational modes (see, for example, Ref. [1]).

Vibrations of atoms near equilibrium positions in a defect occur with local vibrational mode frequency $\omega_E \propto (M_0/M)^{1/2}$, where M_0 and M are the masses of lattice and defect atoms, respectively (Einstein's model). Hence, isotopes of the defect atom will affect ω_E . Lattice atom isotopes, which are neighbor to the defect, should affect "local" M_0 value, also causing variation in ω_E . Intensities of relevant vibrations will combine if several lattice atoms are situated in so-called neighbor shells, equivalent positions in relation to the defect (similar to

the SHF interactions in ESR). However, such effect should decrease sharply with the distance from the defect.

Change in the local vibration frequency may modify the interaction terms of the spin Hamiltonian if a local interatomic potential has significant anharmonic terms and/or if an interaction term nonlinearly depends on atom displacement amplitude. In one and/or both cases, the ESR signal splits up into a number of peaks defined by the total number of isotopes and the defect structure. The intensity of each peak is determined by the isotopic abundance and number of lattice sites in the relevant shell.

Isotopic shifts have been observed for hyperfine (HF) and superhyperfine (SHF) interaction terms [2–7] and for the ZFS term [8–12] of the spin Hamiltonian in various systems, including Si. However, the small magnitude of the effect prevented detailed investigation. Some theoretical aspects of the effect were also considered [13,14].

In the first part of our report [15], we presented results on unique properties of new TU2 and TU3 ESR spectra in Si and identified the composition of the related defect. Herein, we consider the microscopic structure of the defect, the HF and SHF terms and isotopic shifts in the ZFS term of the spin Hamiltonian.

2. Experimental

Details of sample preparation and experimental procedures are given in the first part of the report [15]. Peaks related to the HF and SHF splitting in the TU2 and TU3 spectra were not well resolved. Moreover, peaks related to the isotopic shifts in the ZFS term complicated the spectra. To determine the positions and intensities of the individual resonance peaks, it was necessary to decompose the spectra.

Fitting of experimental spectra from samples doped with natural iron was carried out only after the isotopic shifts related to iron isotopes and HF splitting parameters were determined from analyses of Si samples enriched with ^{57}Fe and ^{54}Fe isotopes. All experimental spectra were fitted with the same, the least possible number of individual peaks having similar width and shape (a derivative of Gaussian function). Intensity of each peak was defined from the main peak, i.e. the $^{56}\text{Fe}^{28}\text{Si}$ isotope peak, using isotopic abundances and the supposed number of equivalent neighbor Si atoms in a shell. The width and intensity of the main peak were allowed to vary with a change in sample orientation.

3. Results and discussion

In Figs. 1a and b, the experimental and fitted spectra are presented together with “stick diagrams”. Similarly, precise fits were obtained for all sample orientations toward the static magnetic field except in the close vicinity of the “transient orientations” [15], where fitting was complicated by the small intensity and large width of the peaks.

The character of angular dependencies of the HF/SHF splitting and isotopic shifts was similar for all isotopes of iron and Si. In Figs. 2a and b, results obtained for the case of ^{57}Fe isotope are presented as a typical example. These data were obtained directly from experiments on ^{57}Fe -enriched samples. The fitted parameters for the HF interaction are presented in Table 1. The HF splitting anisotropy was not affected by the isotopic shifts of the ZFS term of the spin Hamiltonian.

From the fitting results for the TU2 and TU3 spectra, the SHF interaction with two shells of equivalent lattice atoms can be separated, one shell containing 3 Si atoms and the other containing 6 Si atoms in equivalent positions. Interestingly, the SHF interaction parameter of the shell with 3 Si atoms is larger than that of the shell with 6 Si atoms in the case of the TU3 spectra. On the contrary, for the TU2 spectra the interaction with atom shell containing 6 Si atoms is stronger. Considering the microscopic structure of the defect, two appropriate lattice sites along the defect axis to a neighboring vacancy can be proposed for the iron atom: a tetrahedral interstitial T_d site (3 Si atoms in the nearest shell and 6 in

Fig. 1. Experimental (symbols) and fitted (thick line) TU3 spectra at $B \parallel [1\ 1\ 0]$ (a) and TU2 spectra at $B \parallel [1\ 1\ 1]$ (b). Thin dashed lines and numbered bars represent individual fitted peaks. Bar height corresponds to relative intensity. Numbers: (1) $^{56}\text{Fe}^{28}\text{Si}$; (2) $^{56}\text{Fe}^{29}\text{Si}$ (6 Si shell); (3) $^{56}\text{Fe}^{29}\text{Si}$ (3 Si shell); (4) $^{56}\text{Fe}^{30}\text{Si}$ (6 Si shell); (5) $^{56}\text{Fe}^{30}\text{Si}$ (3 Si shell); (6) $^{54}\text{Fe}^{28}\text{Si}$; (7) $^{57}\text{Fe}^{28}\text{Si}$. Experimental conditions: $f_{\text{RES}} = 9.064\text{ GHz}$, $T = 11\text{ K}$, B in the $(1\ \bar{1}\ 0)$ plane.

the second shell) and a position between the T_d and an antibonding (AB) site (6 Si atoms in the nearest and 3 in the second shell). Thus, we can suppose that the change in the magnitude of the defect spin in the magnetic field [15] is accompanied by modification of defect configuration: the iron atom positioned at the T_d site in the case of TU3 ($S = \frac{3}{2}$) is transferred closer to the AB site along the axis of the defect in the case of TU2 ($S = 1$). This microscopic model for the $(\text{Fe}_I\text{-V})^0$ pair in Si differs from that of substitutional iron $(\text{Fe}_S)^+$ proposed in [12] for the similar samples. However, we can suppose that the suppression of the TU2 and TU3 signal by the illumination, observed in our experiments, is caused by charging and transformation of the $(\text{Fe}_I\text{-V})^0$ pair to the $(\text{Fe}_S)^+$ configuration, responsible for the NL19 ESR spectra.

The magnitude of the isotopic shift of the TU3 spectra is constant in the limits of experimental error for rotation angles that are far from the transient orientations. The fractional change in the ZFS parameter

Fig. 2. $A_-(^{57}\text{Fe})$	26.6 ± 1.4	5.07 ± 0.03
$A_1(^{29}\text{Si}/3\text{Si})$	2.2 ± 0.1	4.51 ± 0.06
$A_2(^{29}\text{Si}/3\text{Si})$	6 ± 2	6.86 ± 0.14
$A_1(^{29}\text{Si}/6\text{Si})$	3.2 ± 0.2	3.10 ± 0.04
$A_2(^{29}\text{Si}/6\text{Si})$	16 ± 2	4.52 ± 0.08

caused by the substitution of ^{56}Fe isotope with ^{57}Fe , calculated using the expression derived in Ref. [13], equals to $\delta D/D \approx -(1.4 \pm 0.2) \times 10^{-4}$. This value is close to that reported in Refs. [8,10,13], but much smaller than that reported for the NL19 spectra [12]. In the vicinity of the transient orientations, the magnitude of isotopic shift significantly increases for the TU3 spectra and emerges for the TU2 spectra.

Table 2

Isotopic splitting (ΔH) caused by iron and lattice atom isotopes in the TU3 spectra for the rotation angles far from the transient orientations

Isotope	Shell	ΔH (mT)
^{54}Fe		0.11 ± 0.02
^{57}Fe		-0.042 ± 0.005
^{29}Si	3 Si	0.046 ± 0.013
^{30}Si	3 Si	0.11 ± 0.02
^{29}Si	6 Si	0.035 ± 0.012
^{30}Si	6 Si	0.12 ± 0.02

In Table 2 experimental splitting magnitudes are presented for various isotopes and lattice atom shells in the case of the TU3 spectra. These data are calculated for rotation angles that are far from the transient orientations. It is clearly seen that isotopes of iron and those of the surrounding Si atoms modify the ZFS parameter in an opposite manner. A similar phenomenon was previously reported for the Sn–vacancy pair in Si [10] and agrees with Einstein's model. The shift magnitudes can also be fitted well with the $(M_0/M)^{1/2}$ dependence. In the limits of experimental errors we did not detect variation in the magnitude of the isotopic shifts with temperature in the range from 6 to 18 K.

Obtained results agree with the model for isotopic shifts [13] when sample rotation angle is far from the transient orientations. Observed anisotropy and large magnitude of the effect near the transient orientations requires further investigation and explanation. One possibility is to suppose that the amplitude of iron atom vibration close to the transient orientations becomes much larger due to the changes in defect structure, causing an increase in the isotopic shifts.

In conclusion, two different spin values for the ESR spectra of the iron–vacancy pair in silicon are related to the defect structure with different positions of iron atom along the axis to a neighboring vacancy. The TU3 spectra with $S = \frac{3}{2}$ originate from the configuration in which an iron atom is positioned at the T_d site, while the TU2 spectra with $S = 1$ originate from the defect with iron positioned between the T_d and AB sites. The cause of the observed transition remains to be established. The existing models for the isotopic shift cannot explain the anisotropy and large magnitudes of the shifts observed near the transition orientations.

Evolution of copper–hydrogen-related defects in silicon

S. Knack^{a,*}, J. Weber^a, H. Lemke^b, H. Riemann^b^a*Dresden University of Technology, 01062 Dresden, Germany*^b*Institute for Crystal Growth (IKZ), Berlin, Germany*

Abstract

Copper-implanted silicon and floating-zone silicon doped with copper during crystal growth have been studied by means of capacitance spectroscopy (deep-level transient spectroscopy, DLTS) and photoluminescence (PL). The hydrogen was incorporated by either wet-chemical etching or hydrogen-plasma treatment. The evolution of defects after the incorporation of the impurities and further annealing steps was investigated. PL in combination with DLTS was used to unambiguously identify the copper–copper pair and clarify a recent controversy about the identification of the 1.014 eV luminescence line. Drift and diffusion experiments provide an insight into the structure of this center. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Copper; Hydrogen; Silicon; Defect reactions

1. Introduction

Copper impurities in silicon have been studied for a very long time. Recently, there has been a renewed interest in this field, which has been fueled by new applications of copper in semiconductor technology. Copper metalization for computer chips needs detailed knowledge about copper-diffusion [1,2] and suitable diffusion barriers in silicon. A defect which has been intensively studied recently was originally assigned to be a Cu-pair defect [3–5] and has now been re-interpreted in the light of a new PL-study as a defect containing a single Cu-atom [6,7]. The interstitial copper-species displays some similarities to the behavior of hydrogen in silicon: Both are fast diffusers, which is especially true for Cu; they can both form neutral complexes with shallow acceptors, where the hydrogen-complexes are thermally more stable; and both species can undergo reactions with many intrinsic or impurity defects [8]. In this paper we present data that confirm the original assignment of a Cu-pair defect and we also give details

of the interaction of copper-related defects with hydrogen.

2. Experimental

The defect reactions of copper and hydrogen were studied in two different sets of samples. (A) Copper was dissolved in the melt of silicon and incorporated into the crystal during the floating zone growth process. The boron concentration of the p-type crystals was about $2 \times 10^{15} \text{ cm}^{-3}$. A second p-type crystal was Cu-doped with the same technique but contained grown-in dislocations. The boron concentration for the dislocated crystal was about $1 \times 10^{14} \text{ cm}^{-3}$. (B) A set of p-type floating zone silicon with a boron concentration of $1 \times 10^{14} \text{ cm}^{-3}$ was copper implanted with various doses at room temperature and afterwards annealed at 700 °C for 30 min.

For copper indiffusion at room temperature, a piece of pure copper wire (99.999%) was dissolved in a mixture of HF : HNO₃ (1 : 6). Before photoluminescence (PL) or deep-level transient spectroscopy (DLTS) measurements samples were either etched in this copper saturated solution or in the same mix of acids without any copper.

PL was excited with the 514.5 nm line of an argon-ion laser and measured at 4.2 K with a liquid nitrogen cooled germanium detector with a standard lock-in technique. The setup used for the DLTS measurements was a home-built system using analogue filtering of the transients and a liquid helium cryostat for measurements down to 40 K.

3. Results

Fig. 1 shows DLTS spectra of the dislocation-free silicon crystal and the PL-spectra from this sample is depicted in Fig. 2a. The zero phonon luminescence line at 1.014 eV is well known and has been extensively studied before [3–7]. In the following, we will call this luminescence center Cu_{PL} following the nomenclature of [6] and likewise denote the DLTS-center at $E_{\text{V}} + 0.1$ eV Cu_{DLTS} . In the as-grown dislocation-free samples these are the dominant centers in PL as well as in DLTS. In the dislocated material neither the PL- (Fig. 2b) nor the DLTS-signal (Fig. 3a) can be found. Instead, the levels for substitutional copper [9,10] and copper-hydrogen complexes [11] were measured with DLTS, while the photoluminescence showed a broad line at 0.807 eV which is related to dislocations [12].

Fig. 1. DLTS-spectra of the melt-doped dislocation-free crystal (a) spectra taken after standard etch, (b) spectra taken after etching in copper solution, (c) spectra taken after an additional annealing step at 250°C for 30 min, and (d) reference sample.

Fig. 2. Photoluminescence spectra of the dislocation-free crystal (a) and the dislocated crystal (b).

Fig. 3. DLTS-measurements of the melt-doped, dislocated crystal (a) spectra taken after standard etch and (b) spectra after etching in copper solution.

In the following, we describe some simple annealing and diffusion experiments performed with the dislocation-free samples: Annealing at 250°C for 30 min almost completely removes Cu_{DLTS} , instead the levels of substitutional copper and of the copper-hydrogen complexes are found (Fig. 1b). In the next step, the annealed sample is etched in a copper-containing solution, which again restores the signal Cu_{DLTS} (Fig. 1c). In a reference sample of FZ silicon with a similar boron-concentration but no Cu-doping, no defects could be detected after etching in the same Cu-containing solution (Fig. 1d).

In the dislocated sample the transformation from the substitutional Cu-defect to Cu_{DLTS} can be seen after etching with a Cu-containing solution (spectra 2b) but is not as efficient as in the dislocation-free material. The dominant DLTS peak comes from a level at $E_{\text{V}} + 0.185$ eV and is labeled $\text{Cu}_{\text{DLTS}}^*$. This level together

Fig. 4. PL and DLTS data of a Cu-implanted sample after annealing at 700 °C for 30 min and rapid quenching to room temperature.

with Cu_{DLTS} is also found in the Cu-implanted samples that have been annealed at 700 °C for 30 min (Fig. 4). PL measurements on the implanted samples detected the features of both Cu_{PL} and a system of lines reported by Henry and coworkers in Refs. [13,14] and labeled as Cu' .

4. Discussion

The annealing and diffusion experiments show that the Cu_{DLTS} can be transformed into the defect attributed to substitutional Cu_{S} [9,10]. The PL measurements show an analogue behavior of the Cu_{PL} defect. Cu_{S} cannot be detected in luminescence, but the experiments are consistent with the former assignment of Cu_{DLTS} and Cu_{PL} to the same copper center [5]. The annealing experiments show that $\text{Cu}_{\text{DLTS,PL}}$ is thermally less stable than the substitutional copper. At room temperature, indiffusing interstitial copper is very efficiently bound to Cu_{S} and restores $\text{Cu}_{\text{DLTS,PL}}$. On the other hand, the defect cannot be formed at room temperature in samples where no Cu_{S} is present before the copper indiffusion. These results clearly suggest $\text{Cu}_{\text{DLTS,PL}}$ to be a copper-pair defect consisting of one substitutional and one interstitial copper atom.

In Ref. [6], Nakamura et al. observed a linear dependence of the Cu_{PL} signal on the total copper contamination. They annealed silicon samples containing varying Cu-concentrations below the solubility limit for 30 min at 700 °C. The intensity of Cu_{PL} then showed a linear dependence on the incorporated copper concentration, which led them to suggest that the defect consists of only one Cu-atom. However, also in terms of the pair-model, the linear concentration dependence of the $\text{Cu}_{\text{DLTS,PL}}$ defect can be understood. The law of mass action gives a quadratic dependence on the total copper concentration for the reaction: $\text{Cu} + \text{Cu} \rightarrow \text{Cu}_{\text{pair}}$.

However, this chemical equation does not describe the formation of the defect properly. The defect formation as evidenced by the above described experiments during annealing is rather a two-step process which can be described as

For very fast quenching after the annealing one can set $T_1 = 700^\circ\text{C}$ and T_2 as room temperature. At the elevated temperature, substitutional copper is formed. The concentration Cu_{S} is thus determined by Eq. (1). In the limit of low copper concentration one would therefore expect $[\text{Cu}_{\text{S}}] = k[\text{Cu}_{\text{tot}}]$, with $k < 1$.

When quenched to room temperature the remaining interstitial copper is still mobile and moves freely until trapped to some defect. The main sink for Cu_i is substitutional copper as copper–boron pairs are not stable at room temperature and the small fraction of Cu_i lost to the surface can be neglected. Thus, if $k > 0.5$ then $[\text{Cu}_i\text{Cu}_{\text{S}}] = [\text{Cu}_i] = (1 - k)[\text{Cu}_{\text{tot}}]$, otherwise $[\text{Cu}_i\text{Cu}_{\text{S}}] = [\text{Cu}_{\text{S}}] = k[\text{Cu}_{\text{tot}}]$. In both cases, the concentration dependence would be linear as observed in the experiment of Nakamura et al. [5].

In the limit of high copper concentration the solubility of substitutional copper at 700 °C would be reached and therefore $[\text{Cu}_{\text{S}}] = \text{const.} = [\text{Cu}_i\text{Cu}_{\text{S}}]$ as no additional $[\text{Cu}_{\text{S}}]$ can be formed at room temperature. Thus, for higher concentrations, a saturation of the copper-pair concentration would be expected as is also experimentally observed. The results from the melt-doped silicon samples support this analysis. In dislocation-free silicon, the copper-pair defect is found after crystal growth. This situation changes in dislocated material where the dislocations are a very efficient trap for the interstitial copper leaving no free interstitial copper at lower temperatures for the formation of the copper pair. From this discussion follows that the observed concentration dependence is consistent with the model of a $\text{Cu}_i\text{Cu}_{\text{S}}$ defect.

In an earlier study, a quadratic dependence of the PL-intensity on the Cu-concentration was found [4]. Here, Cu was incorporated in high concentrations and annealed so that the solubility for different temperatures ranging from 700 °C to 1200 °C was reached. In order to analyze this experiment within our model, the equilibrium concentrations for interstitial copper [15,16] and the vacancy [17,18] as well as the formation enthalpy for substitutional copper [8,19] have to be known. From the different sets of values that can be found in the literature we get $[\text{Cu}_{\text{PL}}] \propto [\text{Cu}_{\text{tot}}]^{2.2 \pm 0.2}$ which is very close to the experimental finding of $[\text{Cu}_{\text{PL}}] \propto [\text{Cu}_{\text{tot}}]^{2.0 \pm 0.2}$. Thus, together with previous experimental results on the symmetry of the center we confirm the original assignment of the $\text{Cu}_{\text{DLTS,PL}}$ signal to a $\text{Cu}_i\text{Cu}_{\text{S}}$ pair.

5. Conclusion

In the light of the annealing and diffusion experiments on copper-doped silicon samples, the concentration dependence of the 1.014 eV luminescence line and the $E_V + 0.1$ eV DLTS center is carefully analyzed and the originally proposed model of a Cu-pair defect revisited. No contradiction to the established model of the Cu_iCu_s defect can be found.

The microscopic origin of Cu^* and $\text{Cu}_{\text{DLTS}}^*$ is not clear. The luminescence feature with a zero-phonon line at 943.7 meV is found in samples with low Cu-contamination and has tetrahedral symmetry [13]. It is shifted in energy by -70 meV from the line at 1.014 eV. The fact that it shows up together with the DLTS-level at $E_V + 0.185$ eV, which is likewise shifted by approximately $+80$ meV from the Cu-pair at $E_V + 0.100$ eV suggests that the DLTS peak and the photoluminescence line are both due to the same defect which shows remarkable similarity to the Cu-pair defect.

Electronic and atomic structure of transition-metal–hydrogen complexes in silicon

P.T. Huy^{a,b,*}, C.A.J. Ammerlaan^a^a Van der Waals–Zeeman Institute, University of Amsterdam, Valckenierstraat 65–67, NL-1018 XE Amsterdam, Netherlands^b International Training Institute for Materials Science, ITIMS Building, Dai Hoc Bach Khoa Hanoi, 1 Dai Co Viet Road, Hanoi, Viet Nam

Abstract

Electron paramagnetic resonance investigations on transition-metal-doped silicon, hydrogenated at high temperature in an environment of water vapor, have revealed three transition-metal–hydrogen related paramagnetic centers Si-NL65, Si-NL64, and Si-NL68, respectively, in the samples doped with platinum, gold, and palladium. The spectra, from the sample preparation conditions, and the experimentally observed hyperfine structures of 1:3:3:1–4:12:12:4–1:3:3:1 for the Si-NL65, 1:2:1–1:2:1–1:2:1–1:2:1 for the Si-NL64, and 1:1 for the Si-NL68 spectrum, were identified as complexes of one-platinum–three-hydrogen (Pt–H₃), one-gold–two-hydrogen (Au–H₂), and one-palladium–one-hydrogen (Pd–H₁), respectively. A detailed analysis of the spin-Hamiltonian parameters of the centers, the transition-metal and hydrogen hyperfine interactions, has been carried out providing adequate materials for establishing electronic and microscopic models of the newly observed centers. © 2001 Elsevier Science B.V. 1. Introduction

The properties of transition-metal–hydrogen complexes (TM–H) in crystalline silicon have been studied intensively in the last 15 years. As a result of this effort, the electronic levels, the local vibrational modes, and the structure of a number of TM–H defects have been identified mostly by deep level transient spectroscopy (DLTS) [1,2], Fourier transform infrared and local vibrational mode (FTIR-LVM) spectroscopy [3,4]. These techniques have given valuable information about the position of the TM–H levels in the band-gap, their electron and hole capture cross sections, local vibrational modes associated with hydrogen, and the numbers of hydrogen atoms as well as their positions within the structure of the defects have been determined. However, little direct information has been obtained

about the microscopic structure and the chemical composition of TM–H related defects as the electron paramagnetic resonance (EPR) has failed to detect TM–H related centers so far. Up to now, the Pt–H₂ center was the only case in which both the structure of the defect, and its electronic properties were convincingly established using the combined results from EPR, IR-LVM, and theoretical calculations [1,2,5–7]. To overcome the handicap, in this paper, we report on the studies of TM-doped hydrogenated silicon by EPR. Three TM–H complexes have been observed and identified as containing one transition-metal atom and one, two and three hydrogen atoms, respectively, for the Pd–H₁, Au–H₂ and Pt–H₃ centers. Symmetries of the centers have been measured and determined as monoclinic-I for the Pd–H₁, triclinic for Au–H₂ and trigonal for Pt–H₃ centers. A detailed analysis of the experimental spectra has been carried out and enabled us to determine spin-Hamiltonian parameters of the centers. It was discovered that although the number of hydrogen atoms in each center is different, the hydrogen hyperfine

*Corresponding author. Tel.: +31-20-5255642; fax: +31-20-5255788.

E-mail address: pthuy@science.uva.nl (P.T. Huy).

interactions are very similar with their isotropic and anisotropic parts of about 10 and 1 MHz, respectively. This common character of observed hydrogen hyperfine interaction is reflected in the electronic and atomic models proposed for the centers in which the hydrogen atoms are concluded to favor the interstitial anti-bonding sites to the silicon nearest-neighbor atoms.

2. Experimental

Phosphorus-doped Czochralski-grown silicon with room-temperature resistivity in the range of 0.75–125 Ωcm was used in this study. The crystal was oriented and cut into bar-shaped samples with typical dimensions of $1.5 \times 1.5 \times 15 \text{ mm}^3$, and with the longest side parallel to the $[0\bar{1}1]$ crystal direction. Transition metals gold, platinum, and palladium were introduced by two different methods, either by evaporation or by rubbing TMs to one or all surfaces of the samples, and then heated at 1200–1300°C for several hours. The hydrogenation process was typically performed at 1250–1300°C for 30 min in the atmosphere of water vapor. After hydrogenation the samples were quenched in water at room temperature, then stored in liquid nitrogen till the first measurement. Magnetic resonance experiments were carried out using a superheterodyne spectrometer operating in the microwave *K*-band with the frequency near 23 GHz. The EPR spectra were measured at temperatures of 4.2–20 K.

3. Results

In the platinum-doped hydrogenated samples, after hydrogenation, depending on the cooling rate of the samples, two different Pt–H related spectra are observed. The first spectrum, which has quite high formation probability and is observable in all samples investigated, is characterized by a typical hyperfine structure of 1:2:1–4:8:4–1:2:1, identifying the well-known Pt–H₂ center [3–5]. The second spectrum, labeled Si-NL65, detectable only under visible-light illumination, has very low formation probability and is observable only in 2 of the 40 samples made with very fast cooling rate. The Si-NL65 spectrum, as depicted in Fig. 1, is characterized by a hyperfine structure with the relative intensity of the spectral lines typically of 1:3:3:1–4:12:12:4–1:3:3:1 as being due to the hyperfine interaction with a platinum atom ($I = 1/2$, 33.8% abundance), and three equivalent atoms with $I = 1/2$, 100% abundance. In Fig. 1 for comparison, the EPR spectrum of the Pt–H₂ center is also given and indicated by dashed arrows. The angular dependence of the Si-NL65 spectrum has been measured for the rotation of the magnetic field in the $(0\bar{1}1)$ plane from a $[100]$ to a

Fig. 1. EPR spectrum of the Si-NL65 center associated with the trigonal Pt–H₃ center observed in the platinum-doped hydrogenated sample under visible-light illumination for the magnetic field $B // [0\bar{1}1]$ direction, $T = 4.2 \text{ K}$, and microwave frequency $f = 22.71369 \text{ GHz}$. The spectrum is characterized by a 1:3:3:1–4:12:12:4–1:3:3:1 hyperfine structure. The Pt–H₂ spectrum with hyperfine structure of 1:2:1–4:8:4–1:2:1 is also observed and is indicated by dashed arrows.

$[0\bar{1}1]$ direction, as shown in Fig. 2, revealing the trigonal symmetry of the underlying defect.

In palladium-doped samples, the experimental results showed that after hydrogenation the EPR spectrum of the Pd_s^- center, which was observed strongly in the samples, has disappeared [8]. The EPR spectrum of Fe_i^0 , and in several samples the spectrum of the Pd–Fe pair, has emerged [9]. No immediate Pd–H spectrum was detected. Practically, the observed disappearance of the Pd_s^- center after hydrogen treatment suggests a possibility that all Pd_s^- centers have been converted to other Pd-related centers including the Pd–Fe pair. But as in the experiments only the Pd–Fe pair is observed with much lower intensity after hydrogenation (or not observed at all), the possibility of formation of Pd–H complexes, which are neutral or non-paramagnetic, has to be taken into account. It is known from DLTS experiments that by annealing the samples at temperatures of 400–550 K, one can promote the conversion processes in which the hydrogen-related centers capture or release one or more hydrogen atoms to form new complexes [10,11]. There is a possibility that the new-formed complexes are paramagnetic and observable by EPR. We therefore have carried out the isochronal thermal annealing of our samples. Results showed that after annealing at 450 K

Fig. 2. Angular dependence pattern of the Si-NL65 spectrum as measured for rotation of the magnetic field in the $(0\bar{1}1)$ plane from the $[100]$ to $[011]$ directions. The experimental data recorded for temperature $T = 4.2$ K and microwave frequency $f = 22.731688$ GHz are presented as solid circles. The trigonal symmetry of the Pt-H_3 is clearly determined.

for 60 min. the EPR spectrum of the Pd_s^- center has weakly recovered. Further annealing revealed the gradual recovery of the Pd_s^- center. At the same time a new EPR spectrum is emerging. This spectrum, labeled Si-NL68 for further reference, achieves its highest intensity after annealing at 500 K for about 120 min, see Fig. 3. One of the difficult points in this experiment is, as can be seen in Fig. 3, the very low intensity of the Si-NL68 spectrum, even at its highest concentration. Also, the spectral lines are superimposed, in many parts, on the much stronger Pd_s^- and P_s^0 spectra. Fortunately, by careful measurements with slower scanning speed and highest resolution, we were still able to collect the positions of all the spectral lines versus the magnetic field when rotated in the $(0\bar{1}1)$ plane from the $[100]$ to $[011]$ directions. The corresponding pattern is shown in Fig. 4 presenting monoclinic-I symmetry for the Si-NL68 center. Especially, at the main directions $[100]$ and $[011]$, where the intensity of the spectrum is higher, we observed extra twofold splitting in each of the spectral lines. This splitting is in the order of 7–10 MHz and is anisotropic, providing evidence for the hyperfine interaction with a nucleus with spin $I = 1/2$ and 100% abundance.

In gold-doped samples, the EPR Si-NL64 spectrum of the Au-H_2 center is recorded directly after hydrogenation.

Fig. 3. EPR spectrum of the Si-NL68 center observed in the palladium-doped hydrogenated sample after an isochronal annealing at 500 K for 120 min. The Si-NL68 spectrum is characterized by a twofold splitting in each of the spectral lines as due to hyperfine interaction with one hydrogen atom ($I = 1/2$, 100%), as shown in the inset. Magnetic field $B \parallel [100]$.

Fig. 4. Angular dependence pattern of the Si-NL68 spectrum observed for the rotation of the magnetic field in the $(0\bar{1}1)$ plane from the $[100]$ to $[011]$ directions, disclosing the monoclinic-I symmetry for the corresponding defect.

tion. The spectrum, as depicted in Fig. 5, as observed under visible-light illumination for the magnetic field about 10° away from the $[011]$ direction, shows a very complicated hyperfine structure with a large number of

Fig. 5. Typical EPR spectrum of the Si-NL64 center observed in the gold-doped hydrogenated sample under visible-light illumination for the magnetic field about 10° away from the $[011]$ direction, with microwave frequency $f = 23.0217$ GHz, at temperature $T = 4.2$ K.

groups of spectral lines. This complexity of the spectrum makes the task of identification of the Si-NL64 center difficult. Fortunately, as shown in an extended view in the inset of Fig. 5, each group of spectral lines of the Si-NL64 spectrum is characterized by a very informative hyperfine structure with the relative intensity of $1:2:1-1:2:1-1:2:1-1:2:1$ which can be attributed to the hyperfine interaction with one gold atom ($I = 3/2$, 100%) and two hydrogen atoms ($I = 1/2$, 100%). The spectrum has the rare low symmetry of triclinic, as given in Fig. 6.

4. TM-H identification

In all cases, from the experimental results as described above, the identification of the spectra as originating from TM-H complexes is directly established (except for ^{105}Pd in the Pd-H₁ center). Firstly, all spectra Si-NL64, Si-NL65, and Si-NL68 are observed after hydrogenation. They all exhibit extra splitting of twofold ($1:1$), threefold ($1:2:1$), and fourfold ($1:3:3:1$) revealing hyperfine interaction with one, two, and three hydrogen atoms, respectively, for the Si-NL68, Si-NL64 and Si-NL65 centers. The Si-NL65 spectrum is observed in the platinum-doped sample simultaneously with the Pt-H₂ spectrum. One can practically view the hyperfine structure of $1:3:3:1-4:12:12:4-1:3:3:1$ as an extended picture of the hyperfine structure of $1:2:$

Fig. 6. Triclinic angular dependence pattern of the Si-NL64 spectrum observed for rotation of the magnetic field in the $(0\bar{1}1)$ plane from the $[100]$ to $[011]$ crystallographic directions. Experimental data recorded at $T = 4.2$ K, microwave frequency $f = 23.0217$ GHz.

$1-4:8:4-1:2:1$ of the Pt-H₂ center in which a third equivalent proton is added. As already concluded for the Pt-H₂ spectrum, the presence of one platinum atom is indicated by the resolved hyperfine splitting related to the ^{195}Pt isotope, nuclear spin $I = 1/2$ and natural abundance of 33.8%, resulting in the characteristic splitting of the resonance in three components with the intensity ratio of about $1:4:1$. Presence of two equivalent hydrogen atoms is revealed by triplet structure with amplitudes scaling as $1:2:1$ of all resonances due to the hyperfine fields created by two hydrogen atoms ($I = 1/2$, 100%). Combination of these interactions produces the hyperfine structure of $1:2:1-4:8:4-1:2:1$ as observed in the experiments. Adding the third hydrogen atom, the hydrogen hyperfine structure becomes $1:3:3:1$. Consequently, the $1:3:3:1-4:12:12:4-1:3:3:1$ hyperfine structure is created when combined with hyperfine interaction due to a single platinum atom. This is the case for the Si-NL65 spectrum of the Pt-H₃ center. A similar interpretation is applied for the Si-NL64 spectrum of the Au-H₂ center. In this case, the observed structure of $1:2:1-1:2:1-1:2:1-1:2:1$ can be explained as due to hyperfine interaction with one gold atom, nuclear spin $I = 3/2$ and 100% natural abundance (generating fourfold splitting) and two equivalent or nearly equivalent hydrogen atoms (generating $1:2:1$ structure). For the Si-NL68 spectrum, due to low intensity of the spectrum, the hyperfine lines which represent the hyperfine

interaction with ^{105}Pd isotope ($I = 5/2$, 22.2%) are not strong enough for observation. The assignment to a Pd-H_1 complex, therefore, is tentative and based on the experimental observation of twofold splitting as due to interaction with one hydrogen atom and the appearance of only palladium-related centers in the investigated samples.

5. Electronic and atomic structure of TM-H complexes

From a summary of the spin-Hamiltonian parameters of the centers, as obtained from fittings of the angular dependencies (Figs. 2, 4 and 6) and results of the standard analysis based on linear-combination-of-atomic-orbitals (LCAO), given in Table 1, one can recognize that the g tensors of all centers largely deviate from $g_e = 2.0023$ of the free electron, implying the incorporation of a transition-metal impurity in the microscopic structures of the centers. The hydrogen hyperfine interaction tensors also show a striking similarity for all centers with isotropic part a of about 10 MHz, corresponding to a very low s -type spin density around 0.7% on the hydrogen positions. The small anisotropic component b^{H} of the hydrogen hyperfine interaction, may be

ascribed to the dipole-dipole interaction between the spins of proton and electron, considered as classical dipoles with separation R . From the observed values of b of around 1 MHz, a distance of $R = 0.4\text{--}0.5\text{ nm}$ is calculated. This value means a distance of $0.4\text{--}0.5\text{ nm}$ between the transition-metal atom and the proton, i.e., the hydrogen atom is anti-bonding to the silicon nearest neighbor. In all cases, the observed centers are stable at room temperature and have low symmetry, trigonal for the Pt-H_3 , monoclinic-I for the Pd-H_1 , and triclinic for the Au-H_2 centers, suggesting the substitutional position for the transition-metal atom. On this basis, the atomic model for each center is proposed, as sketched in Fig. 7, in which the transition-metal atom occupies the substitutional site, the hydrogen atom is interstitial and anti-bonding to a silicon nearest-neighbor atom. The position of the TM atom is depicted with respect to the symmetry of each center. As neutral gold is isoelectronic to negative platinum, quite likely spectrum Si-NL64 corresponds to the $[\text{Au}_s-(\text{H}_2)_i]^0$ center observed in the neutral charged state (the $(\text{Pt-H}_2)^-$ center is observed in negative charge state, see Refs. [3,5]). For the same reason, the Si-NL65 spectrum of the $(\text{Pt-H}_3)^0$ center is observed in the neutral charge state as well.

Table 1

Summary of spin-Hamiltonian parameters and some results of the analysis by the method of linear combination of atomic orbitals (LCAO) for transition-metal—hydrogen complexes

Time-resolved photoluminescence study of Si:Ag

N.Q. Vinh*, M.A.J. Klik, T. Gregorkiewicz

Van der Waals–Zeeman Institute, University of Amsterdam, 65 Valckenierstraat, NL-1018 XE Amsterdam, The Netherlands

Abstract

Photoluminescence band at 780 meV, previously assigned to silver-related centers in Si on basis of indirect arguments, is investigated in detail. For that purpose specially prepared samples doped with isotopically enriched silver are used. The photoluminescence spectrum exhibits characteristic structure consisting of narrow no-phonon lines and lower-energy phonon replicas. We observe isotope shift of the three main no-phonon lines which conclusively shows that silver is incorporated in the microscopic structure of the luminescent defect. From time-resolved photoluminescence lifetime of a few 100 μ s is determined. This is a characteristic fingerprint for recombination of excitons bound to isoelectronic centers. Further insight in the nature of the optically active Ag-related center is obtained from the temperature dependence of the lifetime. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Photoluminescence; Silicon; Silver

1. Introduction

Like other noble metals, silver is an important impurity in silicon. This is due to its interesting physical properties as well as possible applications for device manufacturing. When introduced into silicon, silver gives rise to two levels: an acceptor at $E_c - 0.54$ eV and a donor level at $E_v + 0.34$ eV [1]. The donor level has been observed in optical absorption [2]. Transition at the acceptor were not observed. Also low-temperature photoluminescence (PL) from Si:Ag has been reported. It has been found that silver-doped silicon exhibits a characteristic emission spectrum at 780 meV [3–5]. The photoluminescence spectrum consists of narrow no-phonon lines (termed A, B, C at energies 778.91, 779.85 and 784.31 meV, respectively) which are replicated at lower energies by local phonons. From replica of lines A and B, local phonon energies of approximately 6 and 15 meV were determined. At temperatures higher than 20 K phonon replicas of the C line were also

observed. The structure of the 780 meV band was identified as transitions from the effective-mass-theory electronic states near the conduction band to the ground state.

In the present work, we report on observation of the silver isotope shift of the no-phonon A, B, and C lines of the 780 meV band, providing direct microscopic evidence of silver involvement in the center responsible for this emission. Also, the decay time of these lines and its temperature dependence have been determined.

2. Experimental

The starting material for sample preparation was float-zone, p-type silicon, with resistivity of 75–125 Ω cm. Silver was introduced into the sample by evaporation, followed by diffusion at 1150°C for 4 h in a closed quartz ampoule containing 100 mbar of argon. After the diffusion step, samples were quenched to room temperature in water and chemically cleaned to remove the silver-rich surface layer. For diffusion both natural and isotopically enriched silver (99.5% of ^{107}Ag and 99.4% ^{109}Ag isotope) were used.

The PL experiments were performed with a variable temperature continuous-flow cryostat accessing the 1.5–300 K range (Oxford Instruments Optistat CF). For excitation a cw argon-ion laser operating at 514.5 nm was used. All spectra were obtained with a 1.5 m F/12 monochromator (Jobin-Yvon THR-1500) and detected by a high-sensitivity germanium detector (Edinburgh Instruments).

Time-resolved measurements were carried out using a digital oscilloscope (Tektronic TDS 3000) in combination with an InP/InGaAs nitrogen-cooled photomultiplier tube (Hamamatsu R5509-72). For transient excitation a laser beam (at a 1 W continuous power) was passed through a pinhole and mechanical chopping (200 Hz). In this configuration, the experimentally measured system response time was 38 μ s.

3. Results and discussion

3.1. Isotope measurements

For all the investigated samples photoluminescence was measured for the energy range between the band gap energy of silicon and approximately 700 meV. Fig. 1 shows typical photoluminescence spectra obtained in this study from silver-doped silicon samples at 10 and 20 K. The band around 780 meV is similar to that observed earlier [3–5], and ascribed to silver on basis of sample preparation. In addition to that, two new and weaker PL bands at 806 and 811 meV, labeled D and E, respectively, were detected.

Fig. 2 presents high-resolution photoluminescence spectra of the 780 meV band recorded for samples doped with silver isotope ^{107}Ag , silver isotope ^{109}Ag and natural silver. The spectra of samples doped with isotopically enriched silver are similar to that in Fig. 1

Fig. 1. 780 meV PL band observed in silver-doped silicon at $T = 10$ and 20 K.

Fig. 2. A, B and C PL lines measured in silicon doped with isotopically enriched silver (upper curves) and natural silver (lower curve).

but with positions of ABC structure were shifted by ~ -0.017 meV for ^{107}Ag -doped silicon, and by $\sim +0.017$ meV for ^{109}Ag -doped silicon. We also note that PL lines in sample diffused with natural silver ($[^{107}\text{Ag}]:[^{109}\text{Ag}]$ as 52:48) are distinctly broader than those for ^{107}Ag or ^{109}Ag -doping. These results provide direct evidence that silver is involved in the microscopic structure of the center responsible for this emission.

The isotope shifts were observed also for the phonon satellites and are illustrated in Fig. 3 for the 773 and 765 meV replicas of lines A and B. Isotope shifts of luminescence lines are a convenient tool for the identification of the chemical nature of the optically active centers. The isotope effect for the bound exciton photoluminescence is related to the zero vibrations of the center and leads usually to an increase of the recombination energy for heavier nuclei [6,7]. For isoelectronic impurities in silicon such an effect has been experimentally observed for the copper–copper pair [8]. In this case, a 0.1 nm difference of the position of the PL line for the samples doped with ^{63}Cu and ^{65}Cu copper isotopes has been concluded.

In Fig. 4 high-resolution PL spectra of D and E bands at 25 K recorded in samples doped with monoisotopic silver are compared. In this case no isotope shift is observed and we can not conclude whether these lines are silver-related.

3.2. Luminescence decay time measurements

We have examined decay characteristics of A, B and C lines. The decay times are exponential over the entire temperature range and identical for all the components. Fig. 5 shows decay of A line experimentally measured at 4 and 20 K. The lifetimes measured for A line at 4 and 20 K are 248 ± 3 μ s, and 130 ± 5 μ s, respectively. The

Fig. 3. Isotope effect for the phonon replicas of A and B lines.

Fig. 4. Isotope effect for D and E PL lines.

Fig. 5. Decay time for the A line of the 780 PL band measured at 4 and 20 K.

temperature dependence of the lifetime is depicted in Fig. 6. From the comparison with the temperature dependence of PL intensity [3], we assign the

Fig. 6. The temperature dependence of decay times of A and B lines.

high-temperature decrease ($T \geq 30$ K) of the lifetime to dissociation of the exciton. The identical decay time of A, B and C lines is in agreement with the hypothesis that these lines originate from three thermalizing states of the same center [5]. At low temperatures, we obtain long decay times of about 250 μ s. This value is large when compared with the lifetimes of donor or acceptor bound excitons in silicon, which are in the ns range. For excitons bound to a donor or acceptor, the lifetimes strongly depend on the impurity binding energy E_i . Experimentally, approximate dependencies $\tau \propto E_i^{-4.6}$ for acceptor or $\tau \propto E_i^{-3.9}$ for donor were reported and the lifetime shortening was attributed to a localized phononless Auger recombination process [9]. For example, for excitons localized at In acceptors in silicon with $E_i = 154$ meV, the lifetime of $\tau = 2.7$ ns has been determined [9]. The lifetimes measured in this study are by a factor 10^5 longer and are consistent with a model that the A, B and C lines are due to recombinations of excitons bound at an isoelectronic trap [10,11].

5. Conclusion

The 780 meV luminescence lines observed in silver-doped silicon samples have been studied. For samples doped with isotopically enriched silver, we present conclusive microscopic evidence on participation of silver in the optically active center responsible for the 780 meV PL band. The experimentally measured long lifetimes of the three dominant no-phonon lines of the 780 meV band are in agreement with a model of radiative recombination of an exciton localized at an isoelectronic center.

Detection of diffusional jumps of interstitial Fe in silicon by Mössbauer spectroscopy

Abstract

A technique to create radioactive, interstitial ^{57}Fe atoms in silicon at diffusion temperatures is reported, which allows for the detection of their diffusional jumps by the resulting line broadening in the Mössbauer spectra of the emitted 14 keV γ -radiation. Radioactive $^{57}\text{Mn}^+$ ($T_{1/2} = 1.5$ min) ions have been implanted into silicon crystals held at 400–700 K. As a result of the annealing of the radiation damage during the ^{57}Mn lifetime, the Mn atoms are found on substitutional lattice sites. In the subsequent decay of ^{57}Mn to the Mössbauer state of ^{57}Fe , an average recoil energy of 40 eV is imparted on the daughter atom. This leads to a replacement into interstitial sites for the majority of the Fe atoms, the remainder remains on substitutional sites. From the temperature dependent line broadening the diffusion coefficients for neutral and ionised interstitial Fe have been deduced. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Mössbauer spectroscopy; Iron; Silicon; Diffusion

1. Introduction

The controversial experimental results reported for the charge state dependence of the diffusivity of interstitial iron in silicon have been reviewed recently [1]. In particular, Heiser and Mesli [2] found positively charged interstitial Fe_i^+ to diffuse faster than neutral Fe_i^0 . The opposite behaviour was found by Koveshnikov and Rozgonyi [3]. Possible reasons for this discrepancy, related to the techniques and/or the materials applied, were discussed among the authors [4,5] as well as in Ref. [1].

In this contribution, an entirely different approach to solve this issue is reported. ^{57}Fe Mössbauer spectroscopy has been employed, utilising ion implantation of radioactive $^{57}\text{Mn}^+$ parent isotopes at elevated tempera-

tures, where the radiation damage from the implantation is basically annealed during the ^{57}Mn lifetime ($T_{1/2} = 1.5$ min) and the Mn atoms are found on substitutional lattice sites [6]. In the subsequent decay of ^{57}Mn to the Mössbauer state of ^{57}Fe , an average recoil energy of 40 eV is imparted on the daughter atom. This causes a replacement into interstitial sites for the majority of the Fe atoms. A fraction of less than 25% remains on the substitutional sites. Due to their athermal creation in a recoil process the interstitial Fe atoms can be considered as isolated and dilute. A few diffusional jumps of interstitial Fe during the lifetime of the Mössbauer state ($T_{1/2} = 100$ ns) lead to a broadening of their Mössbauer line at $T > 450$ K. This line broadening has been observed previously for interstitial ^{57}Fe in silicon [7] utilising recoil implantation of Coulomb-excited $^{57\text{m}}\text{Fe}$. Here, the implantation and measurement are performed within the lifetime of the Mössbauer state. It turned out that the radiation damage did not anneal out within that lifetime at

E-mail address: hpg@ifa.au.dk (H.P. Gunnlaugsson).

diffusion temperatures and also it was questionable as to whether the interstitial Fe was in the neutral or ionised state [8].

2. Experimental

Radioactive ion beams of $^{57}\text{Mn}^+$ ($T_{1/2} = 1.5$ min) were produced at the ISOLDE facility at CERN using 1.4 GeV proton induced nuclear fission in a UC_2 target and the recently developed laser ion source [9]. Mn atoms were chemically selected via multiple-photon resonant laser ionisation and accelerated to 60 keV. Following mass separation, clean beams of $^{57}\text{Mn}^+$ were obtained. These were implanted into differently doped Si single crystals held at 300–800 K in an implantation chamber. Less than 10^{12} ions/cm² were implanted into each sample to avoid an overlap of the damage cascades during implantation. Mössbauer spectra were recorded with a resonance detector [10] at room temperature mounted on a velocity drive unit outside the implantation chamber. The detector was equipped with four 150 nm thick α - ^{57}Fe absorber layers. This detection method gives a rather complicated 6-fold emission spectrum due to the magnetic hyperfine interaction. However, benefits of this method are the narrow absorber line width and internally calibrated spectra. To allow easier visual inspection of the spectra, the 6-fold emission spectra have been transformed into a single emission feature.

3. Results and analysis

Fig. 1 shows the Mössbauer spectra recorded after implantation into n^+ - (P-doped $1.3 \times 10^{18} \text{ cm}^{-3}$) and p^+ -type (B-doped $3.3 \times 10^{18} \text{ cm}^{-3}$) Si at the temperatures indicated.

Several features can be seen directly in the figure. The general movement of the spectral components towards the right is as expected from the second order Doppler shift. At 475 K, virtually no line broadening is visible and the spectra are dominated by lines assigned to substitutional Fe [11] and interstitial Fe in the tetrahedral site [7,11]. The isomer shift of interstitial Fe is slightly different in n - and p -type material in accordance with the $\text{Fe}_i^{0/+}$ band-gap state [11]. As the temperature is increased to ~ 640 K, a clear broadening of the interstitial lines is observed in both cases. At temperatures above ~ 770 K, the interstitial line has practically disappeared from the spectra, which are now dominated by lines assigned to substitutional Fe and the recently reported new line, which was tentatively assigned to Fe_i -vacancy pairs [12]. Due to the occurrence of this line with increasing temperature, an accurate determination of the line broadening of the interstitial line is hampered.

Fig. 1. Mössbauer spectra obtained after implantation of ^{57}Mn into n -type Si (left) and p -type Si (right) at the temperatures indicated. The thin solid line overlapping the experimental points shows the sum of the fitting components. The thicker lines show the individual components. The black line shows the interstitial line, the dark grey the substitutional line, and the light grey line the new line, which is tentatively attributed to Fe_i -vacancy pairs.

However, in a simultaneous fitting procedure including this line, reasonably accurate values could be determined in the temperature range 500–700 K. As can be seen in the spectra measured at ~ 640 K, the intensity of the new line is too small to affect the immediate conclusion that the line broadening of the interstitial line is larger in p - than in n -type material.

The relationship between the line width of the interstitial line in the Mössbauer spectra, Γ , and the macroscopic diffusion coefficient, D , is given by [13]

$$\Gamma = \Gamma_0 + \frac{12\hbar c D}{E_0 l^2}, \quad (1)$$

where Γ_0 is the experimental line width measured in units of Doppler velocity, \hbar Planck's constant, c the velocity of light, E_0 the energy of the Mössbauer transition ($=14.4$ keV) and l the elementary jump length, 2.35 \AA , assuming jumps between tetrahedral interstitial sites, i.e. a direct interstitial diffusion mechanism. From Eq. (1), it is observed that the line broadening $\Delta\Gamma = \Gamma - \Gamma_0$ is directly proportional to the diffusion coefficient. Fig. 2 shows the line broadening as a function of temperature in n^+ - and p^+ -type (B-doped, $2 \times 10^{19} \text{ cm}^{-3}$) samples.

4. Discussion and conclusions

The electronic consequences of the nuclear decay have been discussed in detail previously [8,11]. For the heavily doped p^{++} - and n^+ -type material employed here, the recoil-produced Fe_i can be safely assumed to be in the

Fig. 2. Line broadening $\Delta\Gamma$ as a function of temperature for two of the samples used in this study. The solid lines represent the expected broadening for pure Fe_i^+ and pure Fe_i^0 charge states for the pre-factors and activation energies indicated.

ionised and neutral charge state, respectively. As seen from Fig. 2, the broadening in p^{++} -type material, i.e. the Fe_i^+ diffusivity is consistently larger than that of Fe_i^0 in the investigated temperature range. It is noteworthy that the broadening for Fe_i^+ is in agreement with the previously determined values [7], corroborating the argumentation [8] that the ionised state prevailed in that experiment. The temperature range, where a good accuracy for the line broadening of the interstitial lines is obtained, is rather narrow. Taking the error analysis into consideration, the pre-factor D_0 and the activation energy E_a of the diffusion coefficient $D = D_0 \exp(-E_a/kT)$ cannot be determined simultaneously with satisfactory accuracy. Using the values given by Heiser and Mesli [2] for D_0 as 10^{-2} and $1.4 \times 10^{-3} \text{ cm}^2/\text{s}$ for neutral and positively charged interstitial Fe, respectively, we obtain activation energies of 0.91(1) and 0.70(1) eV, respectively. While the latter value for Fe_i^+ is in reasonable agreement with the values obtained by Heiser and Mesli [2], 0.69, and Takahashi et al. [14], 0.68, the value for Fe_i^0 is considerably larger than their values of 0.84 and 0.80 eV, respectively. Obviously, the choice of the value for the pre-factor is critical. Taking this value to be $10^{-3} \text{ cm}^2/\text{s}$, common for both states, as suggested in Ref. [1] from an analysis comprising even high-temperature diffusion data, activation energies of 0.66(1) eV for Fe_i^+ and 0.76(1) eV for Fe_i^0 are obtained. The latter value, presumably a lower limit, is still hardly consistent with the value given by Koveshnikov and Rozgonyi [3], 0.56 eV. Irrespective of the difficulties in obtaining accurate values for D_0 and E_a presently, the

diffusivity of Fe_i^+ is found to be larger than that of Fe_i^0 in the temperature range investigated here.

New electron spin resonance spectra from iron-vacancy pair in silicon: I. Defect with two values for the spin

T. Mchedlidze*, M. Suezawa

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan

Abstract

New ESR spectra from an iron-vacancy pair were detected in electron-irradiated float-zone grown silicon samples pre-doped with iron. The paramagnetic center reveals trigonal symmetry. The center is in a neutral state and has two spin values: $S = 1$ when the defect axis direction is close to that of the static magnetic field and $S = 3/2$ for other orientations. The obtained anisotropies of the ESR peak position and intensity suggest a transformation process for the spin magnitude. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Fe; Vacancy; ESR

1. Introduction

Investigation of iron-related defects in silicon (Si) has remained a top priority research topic for more than four decades [1]. Detrimental for Si-based device operation but yet inevitable [2], iron-related defects reveal nontrivial and often unique properties. A large variety of iron complexes with dopant and other impurity atoms in Si have already been detected and studied [1,3]. Less attention, however, has been given to complexes of iron atoms with intrinsic Si defects (vacancies and self-interstitials). Several ESR spectra (named NL19-25) from iron-doped and subsequently electron-irradiated Si samples have been reported previously [4]. Among them, NL19 was interpreted to originate from a positively charged substitutional iron atom (Fe_S^+). If confirmed, this will be the first clear evidence of the existence of Fe_S in Si.

Recently, in similar samples, we detected new ESR spectra, which exhibit two values for the spin of the defect depending on the angle between the crystal axes and magnetic field. We herein present the results of our observations.

2. Experimental

We investigated float-zone grown n-type (phosphorus doped) and p-type (boron doped) Si samples of various resistivities. Mechanically and chemically polished Si samples, $3 \times 3 \times 12 \text{ mm}^3$ in size, were dipped in a 100 ppm FeCl_3 water solution, dried, and annealed at $1000\text{--}1200^\circ\text{C}$ in evacuated quartz capsules for iron doping. Natural iron or that enriched with ^{57}Fe or ^{54}Fe isotope was used for FeCl_3 preparation. Samples were quenched in iced water after doping. Iron-doped and reference samples were irradiated at room temperature with 3-MeV electrons (dose range $d = 0.1\text{--}1 \times 10^{17} \text{ e/cm}^2$) and were kept at temperatures below -10°C after irradiation.

We used a JEOL X-band ESR spectrometer with a TM_{011} mode microwave (MW) resonator and a continuous helium gas-flow cryostat. It was possible to illuminate the samples during measurements. The derivative of MW field absorption with respect to magnetic field ($\partial\chi''/\partial H_0$) was measured using a lock-in amplifier and magnetic field modulation with an amplitude of $0.1\text{--}0.6 \text{ G}$ and a frequency of 100 kHz . The spectra from the iron-related defect were observed in the temperature range from 6 to 18 K. We were not able to conduct measurements below 4.5 K for observation of the NL19 spectra in our samples.

3. Results and discussion

In Fig. 1a, the anisotropy of the ESR peak positions is presented for the $[1\bar{1}0]$ rotation axis together with fitting curves. Expression for the spin Hamiltonian and the fitted parameters are presented in Table 1. (We used factor $P\{\text{mT}\} = g \times 4.66855 \times P\{10^{-4}/\text{cm}\}$ for conversion of energy units [5].) The paramagnetic center of trigonal symmetry (axis $C_3 \parallel \langle 111 \rangle$) was identified. Large zero-field splitting (ZFS) prevented detection of multiple ESR transition lines. We calculated ZFS parameters using the method described in [6]. The ESR signals could not be detected if the direction of the static magnetic field B was within the range of 12° – 18° from C_3 (“transient orientations”). In Table 1 and below, the spectra observed within the range $C_3 \pm 12^\circ$ are termed “TU2” and those observed outside of $C_3 \pm 18^\circ$ are designated as “TU3”. Close to the transient orientations, the amplitude of the ESR signal decreased and its width increased until the signal could not be separated from the experimental noise. Fig. 1b presents the anisotropy of the TU2 and TU3 signal intensity: $I = \int \int (\partial\chi''/\partial H_0) dH_0^2$.

The TU2 and TU3 spectra were detected in all iron-doped and e-irradiated samples except in a low

resistivity ($1.1 \Omega \text{cm}$) p-type sample. The intensity well correlated with interstitial iron concentration in the samples $I(\text{TU2}, \text{TU3}) \propto (C(\text{Fe}_i))^{0.2}$ and with the total irradiation dose $I(\text{TU2}, \text{TU3}) \propto d^{0.75}$. The $C(\text{Fe}_i)$ was estimated using the intensity of the relevant ESR signal with a g -factor of 2.069. $I(\text{TU2}, \text{TU3})$ was larger in samples with high starting resistivity. The ratio $I(\text{TU2})/I(\text{TU3})$ was the same in all measured samples for fixed experimental conditions such as directions, temperature and microwave power. Data illustrating the above statements are presented in Fig. 2. Both the TU2 and TU3 spectra were similarly suppressed by illumination of the sample with white light during the measurements. MW power saturation behavior, temperature dependence of signal intensity and relaxation times of the TU2 spectra differed from those of the TU3 spectra.

The shape of the ESR spectra at the positions indicated as “A” and “B” in Fig. 1a and various iron isotope compositions are presented in Fig. 3a–f. The shape of the TU3 signal (see Fig. 3a) remains

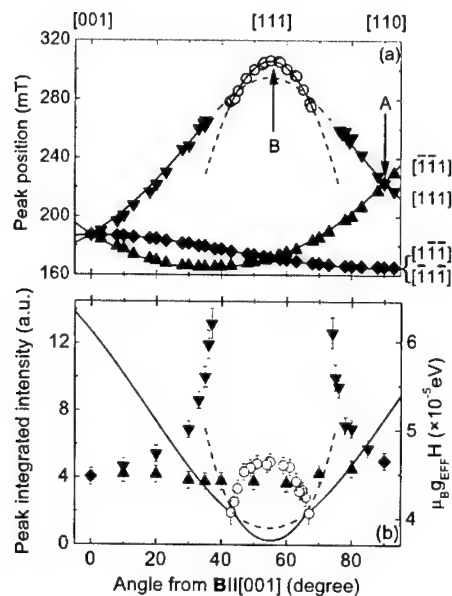

Fig. 1. (a) Measured (symbols) and calculated (lines) anisotropy of peak positions for TU2 (O) and TU3 (other symbols) spectra. Positions corresponding to dotted lines could not be observed. Axes of relevant defects are shown to the right of the graph. (b) Anisotropy of intensity (same meaning of symbols) for the TU2/TU3 signals, values for $[1\bar{1}\bar{1}]$ and $[\bar{1}11]$ axes are not shown. Lines represent anisotropy of spin-transition energy. Experimental conditions: $f_{\text{RES}} = 9.064 \text{ GHz}$, $T = 11 \text{ K}$, B in the $(1\bar{1}0)$ plane.

Fig. 2. $I(\text{TU2})$ (open symbols) and ratio $I(\text{TU2})/I(\text{TU3})$ (★) dependence on $C(\text{Fe}_i)$. Samples: p-type Si (□) $1800 \Omega \text{cm}$; (▽) $5 \Omega \text{cm}$; n-type Si (○) $1000 \Omega \text{cm}$; (△) $0.6 \Omega \text{cm}$. The ratio was calculated for A (TU2) and B (TU3) positions shown in Fig. 1a. Irradiation dose = $5 \times 10^{16} \text{ e/cm}^2$. Lines are presented to guide the eye. All experimental conditions were as indicated in Fig. 1.

Fig. 3. Shapes of the signals corresponding to A (a, c, e) and B (b, d, f) positions in Fig. 1a. Iron isotope composition: (a, b) natural; (c, d) $\sim 50\%$ ^{54}Fe enriched and (e, f) $\sim 70\%$ ^{57}Fe enriched. All experimental conditions were as indicated in Fig. 1.

asymmetric for all directions where it can be detected. Small asymmetry for the TU2 spectra was detected close to the transient orientations. For the samples enriched with ^{57}Fe isotope, the center of gravity for the hyperfine (HF) $^{57}\text{Fe}^{28}\text{Si}$ satellite peaks of the TU3 spectra obviously differs from the position of the $^{56}\text{Fe}^{28}\text{Si}$ related peak (Fig. 3e), and for the samples enriched with ^{54}Fe isotope, isotope-related splitting is clearly observable (Fig. 3c). These observations unambiguously suggest the presence of an isotopic shift [7,8] in the ZFS term of the spin Hamiltonian. Due to the isotopic shifts, the HF/SHF terms in the spin Hamiltonian require special treatment and will be presented in the second part of our report together with a microscopic structure of the defect [9].

The above experimental results (see Figs. 2 and 3) suggest the presence of a single iron atom and a vacancy in the defect. The dependence of defect concentration on sample resistivity may be attributed to the capture of vacancies by phosphorus during irradiation in the n-type samples and to a smaller Fe_i concentration in p-type samples due to iron-boron pairing.

Let us now discuss the observed two spin values for the same defect. Different charge states can bring about different values of the spin for the Fe–V defect. Well-known Fe_i^0 and Fe_i^+ states of interstitial iron are the best example of such situation. However, the observed independence of the $I(\text{TU2})/I(\text{TU3})$ ratio (see Fig. 2a, solid star symbols) from sample conducti-

vity type, resistivity, irradiation dose and illumination conditions contradicts such an explanation. Besides, the observed anisotropy of the signal intensity suggests some transition process. To our knowledge, such a phenomenon has not been previously identified.

Based on our findings, we propose the following explanation. The effective spin $S = 1$ for the Fe–V defect can be explained if the iron atom forms strongly directed $4s4p^3$ hybridized orbitals with four Si atoms surrounding the vacancy. $S = 3/2$ can arise if one of the iron electrons is localized in a singlet configuration near a Si atom positioned along the defect axis. In both configurations, the defect remains electrically neutral. If both of these configurations have finite lifetimes, the defect may ‘choose’ a value for the spin that corresponds to a smaller energy of the defect in spin-excited state: $E = \mu_B g_{\text{eff}} H$. According to the experimental results (see Fig. 1b and Table 1), the $S = 1$ state results in lower energy for spin-transition if the direction of the magnetic field is within the $C_3 \pm 12^\circ$ range, while, on the contrary, $S = 3/2$ is “energetically favorable” outside this range. Thus, the spin of the defect will depend on inter-orientation of the defect axis and magnetic field. Another possibility is that the transverse-to-the-defect-axis magnetic field causes the described change in the electron configuration of the defect. Although we cannot exclude such a possibility, it seems to be less probable due to extremely small values of acting transverse magnetic fields for the transient orientations.

In conclusion, new ESR spectra were detected in the iron doped and subsequently electron irradiated FZ–Si crystals. An origin of the signal is an iron-vacancy pair in trigonal symmetry. The ESR center reveals unique property: the spin of the center changes in the magnetic field.

Theoretical study of pressure-induced negative effective U of a tungsten atom in crystalline silicon

I. Kitagawa*, T. Maruizumi

Advanced Research Laboratory, Hitachi Ltd., 1-280 Higashi-Koigakubo, Kokubunji, Tokyo 185-8601, Japan

Abstract

The effects of local stress on the impurity level of tungsten metal in crystalline silicon were analyzed for the first time by using a first-principles computational method. We examined changes in the ionization energy associated with the tungsten impurity under hydrostatic or in-plane pressure of up to 1 GPa. A tungsten atom was located interstitially in the tetrahedral center position in crystalline silicon. It was found that as pressure increases, ionization energy (+/0) decreases, while ionization energy (+/+ +) increases. Moreover, negative effective U appears at around 600 MPa under hydrostatic pressure. This critical pressure is increased by the change of magneto-volume effect to 900 MPa under in-plane pressure. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Metal impurity; Pressure-induced negative effective U ; First-principles calculation

1. Introduction

Impurities and vacancies in semiconductors have localized electronic states. For example, a silicon vacancy has dangling bonds, which consist of sp^3 hybridization, and a transition-metal impurity has a localized d orbital. These localized states produce a deep level in the band gap, which seldom gives rise to the negative effective U phenomenon. The negative effective U of a silicon vacancy is caused by the change in effective electronic correlation with lattice relaxation [1]. In 3d transition metal impurities, an intrinsic electronic negative effective U appears without lattice relaxation [2]. However, the deep level of 5d transition metals in silicon has not been clarified by theoretically. With the dimensions of MOSFET (metal-oxide-silicon field-effect transistor) devices decreasing both horizontally and vertically, and with the use of noble metals as a gate electrode in these devices, it has become critical to understand how the local stress in a silicon substrate affects the ionization energy of metal impurity. Accordingly, we used a first-principles calculation to theoretically investigate tungsten impurities and we analyzed the

effect of various pressure conditions on the tungsten impurities.

2. Methods

The formation energy of defects in silicon in the charged state Q is given as

$$\Omega(Q, \mu_c) = E_D + Q(E_v + \mu_c) - \sum_s n_s \mu_s, \quad (1)$$

where E_D is the total energy of the supercell containing defects, μ_s is the energy per atom (denoted by “s”) in the perfect lattice, and n_s is the number of s atoms in the defect supercell. The electron chemical potential μ_c in Eq. (1) gives the position of the Fermi level in the band gap relative to E_v (the top of the valence band). Average potential correction [3] was used to calculate the position of E_v in the defect supercell. μ_{Si} tends to be saturated as the supercell size increase. The difference between values of μ_{Si} in supercell of 32 atoms and 64 atoms was within 0.001 eV. Moreover, μ_W was obtained from a perfect BCC structure of tungsten. We used a tetragonal supercell with lattice parameters $a = 10.78$, $b = 10.78$, and $c = 5.40$ Å. This supercell contains 32 silicon atoms. A tungsten atom was located in the tetragonal center

Fig. 1. Pressure conditions used in calculation: (a) hydrostatic, (b) in-plane.

interstitial position in the super cell. We applied two pressure conditions to the supercell: hydrostatic pressure of 1 GPa (Fig. 1(a)) and in-plane compression stress of 1 GPa (Fig. 1(b)). Under such pressure conditions, enthalpy was used instead of total energy of the defect supercell.

We performed the calculation of electronic structure by using the first-principles band-calculation package CASTEP [4]. This package solves the Kohn–Sham equations on a plane-wave basis via nonlocal pseudopotentials, that is, the Vanderbilt-type ultra-soft pseudopotential [5]. The electronic exchange–correlation was treated by the spin-polarized GGA (general gradient approximation), in which the exchange–correlation functional given by Perdew and Wang [6] was applied. The cut-off energy of the plane-wave basis set was 200 eV. The SCF convergence criterion per atom was 1×10^{-6} eV, and the tolerance for root-mean-square force was 0.05 eV/Å. To cancel the interaction between defect states in neighboring supercells, MP (Monkhorst and Pack) [7] $2 \times 2 \times 4$ mesh, which includes eight sampling points, was used. Then, prior to the evaluation of the ionization energy, full geometry optimization was done.

3. Results and discussion

To confirm the accuracy of the calculated formation energy, we first calculated the formation energies of a silicon vacancy (Fig. 2). It is important that the effect of k -point sampling on the total energy calculations, as discussed by Makov et al. [8]. In Fig. 2, the calculation result from the MP $2 \times 2 \times 4$ mesh is closer within 0.2 eV to the formation energy in 216 atoms (the gray line; calculated in [3]) than that of $\Gamma + L$ sampling.

Second, the pressure dependence of the ionization energy of the tungsten impurity is shown in Fig. 3. Ionization energy (+/0) is 0.55 eV at zero pressure. Under hydrostatic pressure, ionization energy (+/0) decreases to 0.51 eV at 1 GPa. Under in-plane pressure,

Fig. 2. Calculated formation energy of a neutral vacancy in silicon. The cell size is given on the bottom of each panel. The horizontal gray line indicates the calculation representing a 216-atoms cell by Puska et al. [3].

Fig. 3. Calculated ionization energy plot for W impurity.

ionization energy (+/0) also decreases to 0.45 eV, which is shallower than that under hydrostatic pressure. Ionization energy (+++/+) is 0.39 eV at zero pressure. Under hydrostatic pressure, (+++/+) increases to 0.6 eV at 1 GPa. This abrupt increase of ionization energy (+++/+) causes the negative effective U . Ionization energy (+++/0) is 0.56 eV at hydrostatic pressure of 1 GPa. Under in-plane pressure, ionization energy (+++/+) also increases to 0.47 eV, and ionization energy (+++/0) decreases to 0.46 eV. The negative effective U does not appear under zero pressure. This theoretical result agrees with the experimental one in [9]. The ionization energies cross at around 600 MPa hydrostatic pressure, above, which the negative effective U appears. Under in-plane pressure, the crossing point increases to 950 MPa.

Table 1
Calculated spin moment of tungsten impurity (μ_B /unit cell)

Pressure (GPa)	$Q = 0$	$Q = +1$	$Q = +2$
0	1.00	1.60	0.00
1 (in-plane)	0.98	1.44	1.92
1 (hydro.)	1.00	1.60	0.10

Finally, we focus on the spin moment of tungsten impurity (Table 1). The spin moment is localized near the tungsten atoms under all pressure conditions. When the charge is neutral ($Q = 0$) and positive ($Q = +1$), high-spin states appear under all pressures. When the charge is double-positive ($Q = +2$), low-spin states appear under zero and hydrostatic pressure of 1 GPa, but the high-spin state appears under in-plane pressure of 1 GPa. It is thus concluded that the spin moment of the double-positive charge is influenced by the pressure condition.

From all the above results, we can investigate the mechanism of ionization energy of a 5d transition metal. It is known that a 5d transition metal, such as tungsten, has strong d-p hybridization between neighboring silicon and metal atoms and weaker exchange splitting than 3d transition metals [10]. These imply that the ionization energy, which is related with the spin-states of the metal, is affected under pressure condition. The volume of a tetrahedral cluster of nearest-neighbor silicon around tungsten is denoted by V and its spin moment is denoted by m_s . The change of volume-magnetic ratio is denoted by $|\Delta V/\Delta m_s|$, which is shown in Table 2. The magneto-volume interaction was changed under various pressures. Under zero pressure, $(|\Delta V/\Delta m_s|)^{0 \rightarrow 1}$ is larger than $(|\Delta V/\Delta m_s|)^{+1 \rightarrow +2}$, while $(|\Delta V/\Delta m_s|)^{0 \rightarrow 1}$ is less than $(|\Delta V/\Delta m_s|)^{-1 \rightarrow -2}$ under both 1 GPa pressure conditions (i.e. in-plane and hydrostatic). This difference between the zero pressure and the 1 GPa pressure conditions is therefore considered to be the origin of the negative effective U of tungsten in silicon. Under in-plane pressure, moreover, the high-spin-state and the large change of the volume-magnet ratio appear and the crossing point increases from 600 to 950 MPa. From our results, it is implied that the effect of

Table 2
Calculated $|\Delta V/\Delta m_s|$ of a tetrahedral cluster of nearest-neighbor silicon around tungsten

Pressure (GPa)	$Q(0 \rightarrow +1)$	$Q(+1 \rightarrow +2)$
0	0.075	0.056
1 (in-plane)	0.000	0.281
1 (hydro.)	0.075	0.150

magneto-volume on the ionization energy is larger than that in 3d transition metals.

4. Summary

We performed first-principles calculations of the electronic and geometrical structures of tungsten impurity in crystalline silicon. It was found that as pressure increases, the ionization energy ($+ / 0$) decreases, while ionization energy ($+ + / +$) increases. Negative effective U appears around a hydrostatic pressure of 600 MPa. It was also found that the change of magneto-volume effect increases this critical pressure to about 900 MPa under in-plane conditions.

Abstract

To examine the site-exchange mechanism of nickel atoms in dislocation-free silicon, the effect of nickel precipitates on the in-diffusion and annealing rates has been investigated. The variation of the concentration of substitutional nickel atoms with time in these processes follow well the theoretical prediction for the dissociative mechanism. It is suggested that nickel atoms in dislocation-free silicon exchange their sites via the dissociative mechanism, or the dominant point defects mediating the site exchange are vacancies. In-diffusion and annealing processes of nickel atoms are accelerated by the presence of the nickel precipitation, indicating that nickel precipitates, or precipitation-induced lattice defects play a role of sinks and sources of vacancies in the bulk. © 2001 Elsevier Science B.V. Keywords: Silicon; Nickel; Precipitation; Enhanced site-exchange rate

1. Introduction

Diffusion and electrical properties of 3d transition elements in silicon have been investigated by many researchers [1–4] from technological and scientific viewpoints. Among 3d transition-metal impurities in silicon, nickel is known to be a peculiar impurity because of the following reasons: First, nickel atoms occupy both substitutional and interstitial sites in silicon crystal. Second, while a large fraction of total atoms is interstitially dissolved, only substitutional atoms whose fraction are in the order of 10^{-3} to 10^{-4} of total dissolved atoms are electrically ionizable [5]. For this reason, nickel is a useful impurity for examining the site-exchange mechanism of impurity atoms in silicon by using an electrical measurement.

It has been proposed [5–7] that the site exchange of nickel atoms in dislocated silicon proceeds via a dissociative mechanism or a vacancy mechanism. In dislocated silicon, both the crystal surfaces and the dislocations act as sinks and sources (SS) of vacancies.

However, the site-exchange mechanism in dislocation-free silicon is an open question, since the experimental confirmation is still limited except for only a few studies [4,8–10]. We have recently proposed [8–10] that the site exchange of nickel atoms in dislocation-free silicon is due to the dissociative mechanism and that the crystal surfaces and a small fraction of nickel precipitates in the bulk can act as the SS of vacancies. The presence of inner SS may lead to an enhancement of site exchange rate.

The purpose of the present paper is to report the results of the in-diffusion and annealing processes of substitutional nickel atoms in dislocation-free silicon to examine the site-exchange mechanisms. It will be shown that the site exchange rates are enhanced by the precipitation of nickel.

2. Experimental

Starting silicon crystals used in the experiment were n-type, phosphorus-doped and dislocation-free wafers. Phosphorus content ranged from 1.3×10^{13} to $1.4 \times 10^{14} \text{ cm}^{-3}$. Nickel thin films were deposited by vacuum evaporation onto the surfaces of silicon slices.

Nickel diffusion was carried out in flowing nitrogen gas ambient at diffusion temperatures. $T_D = 960^\circ\text{C}$. The concentration, C_s , of electrically active nickel atoms, namely substitutional nickel atoms was evaluated by measuring the electrical resistivity by means of the four-point probe method. For the in-diffusion process, C_s was measured as a function of diffusion time, t_D . For annealing process, C_s was measured as a function of annealing time, t_A , at an annealing temperature, $T_A = 960^\circ\text{C}$, after the sample was saturated with nickel at 1020°C . Nickel precipitates were observed using an infrared microscope (Olympus BHSM-IR) and a scanning electron microscopy (SEM, Elionix ERA-8800).

3. Results and discussion

It has been generally assumed that, in the in-diffusion and annealing processes, the distribution of C_s is uniform in the crystal. However, substitutional (or electrically active) nickel atoms are well known to manifest U-shaped distribution in silicon. Based on the observed distribution of C_s [10], we assumed here that the distribution is uniform after removing off a surface layer of thickness of around $0.2l$, where l is the thickness of the sample.

Experimental results are shown in Figs. 1 and 2 for in-diffusion and annealing processes, respectively. Note that Fig. 1 also includes the data for nickel in-diffusion in dislocated silicon. It is stressed here that one experimental point in Figs. 1 and 2 represent the averaged value over the values obtained from a few samples prepared independently. Curves show the theoretical values of Eqs. (1) and (2) predicted by the dissociative mechanism:

$$C_s/C_s^0 = 1 - \exp(-t_D/\tau) \quad (1)$$

Fig. 1. In-diffusion process of nickel in dislocated and dislocation-free silicon crystals at $T_D = 960^\circ\text{C}$. \circ : Dislocated silicon with $l = 0.1\text{ cm}$, \bullet : dislocation-free silicon with $l = 0.1\text{ cm}$, and Δ : dislocation-free silicon with $l = 0.4\text{ cm}$. Curves (a), (b) and (c) are calculated values of Eq. (1) with $\tau = 1.1 \times 10^3\text{ s}$, $6.8 \times 10^3\text{ s}$, and $2.2 \times 10^4\text{ s}$, respectively.

Fig. 2. Annealing process of nickel in dislocation-free silicon at $T_A = 960^\circ\text{C}$. The sample was first saturated with nickel at $T_D = 1020^\circ\text{C}$ ($C_s^i \approx 8.5 \times 10^{13}\text{ cm}^{-3}$). Curves (a) and (b) are the calculated values of Eq. (2) with (a) $\tau = 1.0 \times 10^4\text{ s}$ ($l = 0.05\text{ cm}$), and (b) $\tau = 4.3 \times 10^4\text{ s}$ ($l = 0.2\text{ cm}$).

for the in-diffusion process and

$$(C_s^i - C_s)/(C_s^i - C_s^0) = 1 - \exp(-t_A/\tau) \quad (2)$$

for annealing process. In Eqs. (1) and (2), superscripts 0 and i are the thermal equilibrium concentration and the concentration at $t_A = 0$, respectively. The experimental results agree well with the theory of the dissociative mechanism, suggesting that the dominant point defects mediating the site exchange of nickel atoms are vacancies as in the case of dislocated silicon [6,7]. However, in the annealing process, it has not yet been confirmed experimentally whether $(C_s^i - C_s)/(C_s^i - C_s^0)$ depends on C_s^i or not [6,7]. Furthermore, diffusion profile of C_s cannot exclusively determine the site-exchange mechanism [10]. We infer that these difficulties originate from the presence of nickel precipitates in the bulk, which will be discussed below.

Nickel precipitates in the crystal bulk of dislocation-free silicon. The nickel precipitates, which were identified by comparison between infrared microscope images of nickel-doped and undoped silicon crystals, are potential candidates for SS of vacancies. Nickel precipitates was confirmed by SEM observation. The radius of precipitates ranged typically from 1 to $3\text{ }\mu\text{m}$.

Fig. 3 shows the precipitation density, n_{pr} , as functions of t_D and T_D in the in-diffusion process at the center of the crystal. It can be seen that n_{pr} increases monotonically with the increase of t_D and T_D . This suggests that the precipitation process proceeds during the heat treatment as well as the quenching processes, and that heterogeneous nucleation sites of the precipitation are present in the bulk of dislocation-free silicon. Although the type of nucleation sites is unknown, spontaneous nucleation at the strain centers such as grown-in defects would be possible. Precipitates were observed only in the case of rapid quenching. Furthermore, any nickel precipitate in the bulk could not be

Fig. 3. The precipitation density, n_{pr} , as functions of T_D (°C) and t_D (s) in the in-diffusion process at the center of the crystal. Samples were prepared with the cooling rate of about 90°C s^{-1} .

observed after the heat treatment at temperatures lower than 860°C .

It has been reported [4,8–10] that the nickel precipitates accelerate significantly the site exchange rate, $1/\tau$, of nickel. Nickel precipitates formed at high temperatures or precipitate-induced lattice defects such as bound dislocations [12] possibly play a role as SS of vacancies. If the crystal surfaces and inner defects act as SS, $1/\tau$ in the in-diffusion and annealing processes may be described as [13,14]

$$\frac{1}{\tau} = \frac{C_v^0 D_v}{C_s^0 + C_v^0} \left[\left(\frac{\pi}{l} \right)^2 + G_{SS} \right], \quad (3)$$

where C_v^0 and D_v are the thermal equilibrium concentration and diffusion coefficient of vacancies, and $(\pi/l)^2$ describes the contribution from the surface SS to τ^{-1} and G_{SS} the contribution from the inner SS. If the spherical inner SS with radius r_0 is randomly distributed with the effective volume density, N_{SS} , in the bulk, G_{SS} can be given by [13]

$$G_{SS} = 4\pi r_0 N_{SS}. \quad (4)$$

Experimental data of τ in Figs. 1 and 2 are plotted as a function of l^2 in Fig. 4 in which the value of τ at $l^2 = 0.01 \text{ cm}^2$ is normalized to unity. Broken curves show the calculated value of Eqs. (3) and (4) with the N_{SS} values shown in the figure. The theoretical values of τ for $N_{SS} \approx (2-3) \times 10^5 \text{ cm}^{-3}$ in the in-diffusion process and for $N_{SS} \approx 3 \times 10^6 \text{ cm}^{-3}$ in the annealing process seem to fit qualitatively to the experimentally obtained values of τ . Thus precipitates or presumably precipitate-induced lattice defects may lead to the acceleration of the site-exchange rate of nickel in dislocation-free silicon. The site exchange of nickel atoms may be limited by the vacancy diffusion in the crystal from the SS since diffusion coefficient of vacancies is much lower than that of interstitial nickel atoms [6,7].

Fig. 4. Relationship between τ and l^2 in the in-diffusion process (●) and annealing process (○). The values of τ at $l^2 = 0.01 \text{ cm}^2$ are normalized to unity. Broken lines show the calculated values of Eqs. (3) and (4) with N_{SS} values indicated in the figure.

In dislocated silicon, on the other hand, it has been established [7] that both dislocations and crystal surfaces are the SS of vacancies. Hence the in-diffusion and annealing processes of substitutional impurity atoms are limited by the slower process, whether the generation and annihilation of vacancies at the SS or the diffusion of vacancies in the crystal. In order to compare the values of τ of the in-diffusion process between dislocated and dislocation-free silicon, we have re-examined the in-diffusion process for dislocated silicon crystals with dislocation densities, n_d , from 1.7×10^4 to $2.1 \times 10^4 \text{ cm}^{-2}$. It was found [10] that C_s varies with t_D in accordance with Eq. (1), and that $\tau n_d \approx 2 \times 10^7 \text{ s cm}^{-2}$ which is very consistent with the reported results [6,7] in which τn_d ranged from 2.1×10^7 to $3.5 \times 10^7 \text{ s cm}^{-2}$. This result indicates that the product τn_d is invariant for the dislocated silicon samples. The time constant, τ , of in-diffusion process (and also of annealing process, see Ref. [7]) is then inversely proportional to n_d . A reasonable explanation for this relation is that G_{SS} may be given by $G_{SS} = 2\pi n_d / \ln(r_d/r'_0)$ [6,7], where r_d and r'_0 are the half mean distance of dislocations and the effective radius of a dislocation for capturing a vacancy, respectively. Therefore, τn_d may be constant if dislocations are the dominant SS of vacancies.

Since the diffusion coefficient, of interstitial nickel atoms is high [5] and the solubility decays exponentially with the decrease of temperature [11], interstitial nickel atoms may diffuse out to the surface and/or form precipitates in the bulk. Seibt and Schröter [12] have revealed the morphology, structure and composition of nickel precipitates in the bulk. They [12] also proposed the model that the growth of the precipitates proceeds exclusively by the diffusion of interstitial nickel atoms to the dislocations bound to precipitates. Although we have not been successful to observe the bound dislocations, we consider that the bound dislocations play a

role of the SS of vacancies. To our knowledge, a series of our studies [4,8–10] is the first observation of the enhanced site-exchange diffusion in transition-metal impurity atoms in dislocation-free silicon due to the presence of precipitates or precipitation-induced lattice defects.

In summary, it was suggested that nickel atoms in dislocation-free silicon exchange their sites by the dissociative mechanism, i.e., the dominant point defects mediating the site exchange are vacancies. Nickel precipitates in dislocation-free silicon as well as in dislocated silicon. The crystal surfaces, and nickel precipitates or precipitate-induced lattice defects were found to play a role as the SS of vacancies, which increases significantly the site exchange rates.

Abstract

The diffusion of implanted ^{195}Au in amorphous Si_3N_4 - and Si_4N_3 -layers has been investigated by means of a radiotracer technique. Except for as-produced a- Si_4N_3 , in which pronounced structural relaxation takes place during diffusion annealing, ^{195}Au was found to diffuse via interstitial-like mechanisms. A sudden freezing of the ^{195}Au -diffusivity in pre-annealed a- Si_4N_3 below about 880°C is attributed to a disorder–order phase transition. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: ^{195}Au -diffusion in amorphous Si_3N_4 and Si_4N_3 ; Radiotracer technique; Interstitial-type diffusion mechanisms; Order–disorder phase transition

1. Introduction

The production of Si–(B–)C–N-type ceramics from polymeric precursors plays a significant rôle in the development of advanced materials [1]. In this production route, an intermediate amorphous state is passed from which the final polycrystalline ceramic produce evolves by diffusion-controlled crystallization.

Using polyvinylsilazane as precursor, the intermediate amorphous (a) state is a- $\text{Si}_{28}\text{C}_{36}\text{N}_{36}$. According to neutron- and X-ray-diffraction studies [2], this consists of a- Si_3N_4 and a-C domains. Previous investigations have shown that in a- $\text{Si}_{28}\text{C}_{36}\text{N}_{36}$ the diffusion of ^{71}Ge [3] and ^{195}Au [4] is controlled by the a- Si_3N_4 phase. More specifically, it has been proposed that ^{71}Ge is covalently incorporated and diffuses via smeared-out vacancies, whereas ^{195}Au squeezes through the meshes of the amorphous network in an interstitial-like manner.

Obviously, the preceding proposal how ^{71}Ge and ^{195}Au diffuse in a- Si_3N_4 are solely based on the investigations on a- $\text{Si}_{28}\text{C}_{36}\text{N}_{36}$. Hence, in this work

measurements of the diffusion of ^{195}Au in amorphous silicon nitride have been performed.

A problem in diffusion studies on amorphous solids is the metastability of these materials. This may lead to a structural relaxation during diffusion annealing. To determine the effect of such relaxations, ^{195}Au -diffusivities have been measured on both as-produced and pre-annealed a- Si_3N_4 .

It is not very likely that the amorphous silicon-nitride domains in a- $\text{Si}_{28}\text{C}_{36}\text{N}_{36}$ possess precisely the composition Si_3N_4 . Therefore, the influence of “chemical misfits” was tested by extending our ^{195}Au -diffusion studies on as-produced and pre-annealed amorphous silicon nitride of the composition Si_4N_3 .

2. Experiments

The specimens used in the present diffusion studies were $1\mu\text{m}$ thick layers of a- Si_3N_4 or a- Si_4N_3 , which had been produced by sputter-deposition of Si onto Si-substrates in N_2 -atmosphere. Some of the specimens were pre-annealed for 2 h at 1050°C . The amorphousness of the layers was tested by electron diffraction.

E-mail address: wfrank@mf.mpg.de (W. Frank).

The diffusion measurements were done by means of a radiotracer technique, in which 10^{16} radioactive ^{195}Au -atoms/ m^2 were implanted with a kinetic energy of 60 keV to depths of about 30 nm into $7 \times 7 \text{ mm}^2$ platelet-shaped specimens. The implantations were followed by isothermal diffusion anneals in the temperature regime of 835–1020 °C; the annealing durations were 20 min to 22.6 h. The diffusion profiles $C(x)$ were determined by serial sectioning with the aid of ion-beam sputtering and subsequent sectionwise measuring of the radioactivity ($C = ^{195}\text{Au}$ -concentration, x = depth coordinate). From these, the diffusion coefficients, D , were extracted by fitting an appropriate solution of the diffusion equation.

3. Results and discussion

3.1. Diffusion of ^{195}Au in $\text{a-Si}_3\text{N}_4$

Fig. 1 shows diffusion profiles of ^{195}Au in as-produced (○) and pre-annealed (●) $\text{a-Si}_3\text{N}_4$. Both profiles possess a hump α , where the peak of the implantation profile was located. This arises from ^{195}Au -atoms trapped by implantation-induced damage. The hump δ in the profile of the pre-annealed specimen is due to an accumulation of ^{195}Au -atoms at the $\text{a-Si}_3\text{N}_4$ -Si interface.

In the as-produced specimen, the regime β of the profile reflects the migration of the ^{195}Au -atoms during diffusion annealing. The diffusion coefficients of ^{195}Au in as-produced $\text{a-Si}_3\text{N}_4$ displayed in Fig. 2 (○) were determined from the regime β of such diffusion profiles. They obey an Arrhenius law

$$D = D_0 \exp(-H/kT) \quad (1)$$

with the pre-exponential factor $D_0 = 1.4 \times 10^{-8} \text{ m}^2 \text{ s}^{-1}$ and the diffusion enthalpy $H = 2.5 \text{ eV}$ (k is Boltzmann's constant, T is the temperature). As discussed by Matics and Frank [4] these values indicate that in as-produced $\text{a-Si}_3\text{N}_4$ ^{195}Au undergoes direct interstitial-like diffusion.

Fig. 1. Diffusion profiles of ^{195}Au in as-produced (○) and pre-annealed (●) amorphous Si_3N_4 after diffusion annealing at 933 °C for 16 h and at 932 °C for 16.6 h, respectively. For the discussion of the various parts of the profiles, α – δ , see text.

Fig. 2. Arrhenius plots of the diffusion coefficients of ^{195}Au in as-produced amorphous Si_3N_4 (○) and of ^{195}Au (▲) or ^{71}Ge (◆) in pre-annealed amorphous Si_3N_4 .

In the pre-annealed $\text{a-Si}_3\text{N}_4$ specimen (Fig. 1, ●), the major part γ of the diffusion profile has a shape that is characteristic of diffusion via the kick-out mechanism [5] and thus implies that ^{195}Au diffuses faster than in as-produced $\text{a-Si}_3\text{N}_4$.

A more detailed, admittedly speculative interpretation of the results on the diffusion of ^{195}Au in $\text{a-Si}_3\text{N}_4$ presented above is given in what follows. As in crystalline Si_3N_4 , important building blocks of the continuous random $\text{a-Si}_3\text{N}_4$ network are tetrahedra (in Fig. 3 represented by triangles) with 4 N-atoms at their corners and 1 Si-atom at their centres [6]. In as-produced $\text{a-Si}_3\text{N}_4$ these tetrahedra are damaged, distorted, and not well arranged. These imperfections hamper the direct diffusion of ^{195}Au in as-produced $\text{a-Si}_3\text{N}_4$.

Thermal annealing of $\text{a-Si}_3\text{N}_4$ perfects the tetrahedra and arranges them to establish a short-range order resembling the crystalline Si_3N_4 -structure. In this more perfect $\text{a-Si}_3\text{N}_4$, many neighbouring tetrahedra are grown together at their corners sharing an N-atom. In pre-annealed $\text{a-Si}_3\text{N}_4$, this network of grown-together tetrahedra constitutes paths for rapid diffusion of ^{195}Au . As shown in Fig. 3a, an Au-atom may either substitute an Si-atom (Au_s) or form a mixed dumbbell interstitial (Au_i) by sharing a central tetrahedron site with an Si-atom. The existence of these two configurations of gold atoms is a prerequisite for the operation of a kick-out mechanism [5] in which Au_i migrates by a jump of the Au-atom of the mixed dumbbell into the centre of a neighbouring tetrahedron. There either a new mixed dumbbell is formed or, by releasing a dumbbell Si self-interstitial (I), an immobile Au_s -atom is produced. The

Fig. 3. Schematic illustration of diffusion mechanisms. The triangles stand for tetrahedra whose corners are formed by N-atoms. Empty and full circles represent Si-atoms and foreign atoms, respectively. (a) ^{195}Au -diffusion in pre-annealed amorphous Si_3N_4 (Au_i = mixed Si–Au dumbbell, Au_s = substitutional Au, I = dumbbell Si self-interstitial). (b) ^{195}Au - or ^{71}Ge -diffusion in pre-annealed amorphous Si_4N_3 (1 = reorientation of a mixed dumbbell, 2 = shift of a dumbbell configuration).

reversibility of these processes required for kick-out diffusion is indicated in Fig. 3a by the pair of arrows.

3.2. Diffusion of ^{195}Au in $\text{a-Si}_4\text{N}_3$

As a result of the “chemical misfit” of $\text{a-Si}_4\text{N}_3$, in its as-produced state ^{195}Au -diffusion is superimposed by pronounced concurrent structural relaxation. Hence, meaningful diffusion profiles cannot be measured on as-produced $\text{a-Si}_4\text{N}_3$.

An interesting phenomenon occurs in pre-annealed $\text{a-Si}_4\text{N}_3$. Within the small temperature interval 869–936°C, the diffusivities of both ^{195}Au and ^{71}Ge increase from unmeasurably small values to 10^{-17} and $10^{-19} \text{ m}^2 \text{ s}^{-1}$, respectively, and, at higher temperatures, obey Arrhenius laws (^{195}Au : $D_0 = 3.4 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$, $H = 3.4 \text{ eV}$; ^{71}Ge : $D_0 = 5 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$, $H = 3.8 \text{ eV}$) (Fig. 2). As will be shown below, these sudden diffusivity increases of both ^{195}Au and ^{71}Ge at similar temperatures may be ascribed to a structural phase transition.

In extension of the scenario (Fig. 3a) invoked to explain the diffusion mechanism of ^{195}Au in pre-annealed $\text{a-Si}_3\text{N}_4$ (Fig. 1, ●), we propose that pre-annealed $\text{a-Si}_4\text{N}_3$ may be constructed from pre-annealed $\text{a-Si}_3\text{N}_4$ by replacing 78% of the Si-atoms in the centres of the N-tetrahedra with Si-dumbbells (Fig. 3b). Si self-diffusion in pre-annealed $\text{a-Si}_4\text{N}_3$ is assumed to occur via an interstitialcy-like mechanism in which a Si-dumbbell configuration shifts into a dumbbell-free neighbouring tetrahedron (containing one Si-atom only). If the major axis of the dumbbell does not point to the N-corner shared with a dumbbell-free neighbouring tetrahedron, the dumbbell shift has to be preceded by a

reorientation of the dumbbell. This dumbbell reorientation is assumed to be the rate-controlling step in the Si self-diffusion in pre-annealed $\text{a-Si}_4\text{N}_3$. Conveying this model to foreign-atom diffusion (Fig. 3b), we suggest that ^{195}Au or ^{71}Ge diffuses in pre-annealed $\text{a-Si}_4\text{N}_3$ with the aid of mixed Si–Au or Si–Ge dumbbells in a corresponding manner.

The diffusion mechanisms in pre-annealed $\text{a-Si}_4\text{N}_3$ proposed above lead to a natural explanation of the sudden diffusivity rise of ^{195}Au and ^{71}Ge occurring when the diffusion temperature is raised through the interval 869–936°C. Below this temperature regime the dumbbells are aligned, at least domainwise, in a parallel direction (Fig. 3b, left). In this ferro-elastic state, the reorientation of the dumbbells is blocked and, as a result, diffusion is suppressed. Above this temperature regime (Fig. 3b, right), thermally activated reorientation of the dumbbells is possible. This results in a para-elastic state and enables dumbbell-mediated diffusion to occur.

The fact that the abrupt diffusivity changes of ^{195}Au and ^{71}Ge take place at similar temperatures is in accordance with their interpretation in terms of an order–disorder phase transition of pre-annealed $\text{a-Si}_4\text{N}_3$. Moreover, the similarity of both the diffusion enthalpies and the D_0 -values for ^{195}Au and ^{71}Ge (see above) is not surprising if one accepts that both elements diffuse via dumbbells. The preceding interpretation implies that in pre-annealed $\text{a-Si}_4\text{N}_3$ Si self-diffusion sets in at temperatures similar to the on-set temperatures of ^{195}Au - and ^{71}Ge -diffusion and that the activation enthalpy and the D_0 -value of Si self-diffusion are close to those of ^{195}Au and ^{71}Ge . These predictions permit one to test the preceding interpretation.

Acknowledgements

The authors would like to thank F. Aldinger and his collaborators for their interest in this work, D. Eversheim for his assistance during the ^{71}Ge -implantation at Bonn University, and M. Kelsch for the electron-diffraction studies. Properties of Cr in hydrogenated Si

Y. Sato, T. Takahashi, M. Suezawa*

Institute of Materials Research, Tohoku University, 2-1-1 Katahira, Sendai 980-8577, Japan

Abstract

Properties of interstitial chromium (Cr_i) in hydrogenated p-type Si crystals were studied by means of an EPR method. Specimens were prepared from a floating-zone grown p-type Si crystal. They were doped with Cr by high temperature annealing in Cr vapor, followed by quenching. Then, they were doped with hydrogen (H) by annealing in H_2 gas followed by quenching. We measured their EPR spectra to determine the concentrations of Cr_i and CrB pair. The intensity of EPR spectrum due to Cr_i in hydrogenated Si was about one-tenth of that without H when they were doped at 1250°C. The heat of the solution of Cr in hydrogenated Si was determined to be about 1.9 eV which is much smaller than that (2.9 eV) without H doping. The migration energy of Cr_i in H-doped Si was determined to be 0.70 ± 0.09 eV, which is smaller than that (about 1 eV) without H. Site change from interstitial to substitutional was observed in the specimen co-doped with Cr and Cu. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Hydrogen (H) in Si crystals is chemically active and easily forms pairs and complexes with other impurities and defects. Complexes of H and 5d transition metal impurities have been studied by means of EPR, FT-IR and DLTS methods. Their symmetries, number of H atoms included in the complexes as well as their energy levels have been clarified [1]. On the other hand, studies on complexes of H and 3d transition metal impurities have not been performed well. The 3d transition metals mainly occupy interstitial sites in contrast with 5d transition metals, which mainly occupy substitutional sites. They are harmful for silicon devices from practical viewpoint and have interesting properties from basic viewpoint. Their energy levels were determined by means of the DLTS method [2]. Takahashi and Suezawa studied Fe–H complexes by means of the EPR method [3]. They found that the solubility of Fe changes according to the co-doping of H and also found a new

EPR spectrum due to Fe–H pair. We performed a similar study on Cr. It has been clarified that Cr has properties much different from those of Fe.

2. Experiment

Specimens used in this experiment were cut out from a floating-zone grown silicon crystal of p-type (boron concentration: $2.5 \times 10^{15} \text{ cm}^{-3}$), since positively charged Cr , Cr_i^+ , is easily detected by EPR measurements. After mechanical shaping and chemical etching, Cr was doped by a vapor-pressure method, namely, specimens were sealed in evacuated quartz capsules together with a piece of Cr wire and were heated at appropriate temperature for duration longer than those estimated from the diffusion constant of Cr followed by quenching in water. Next, we doped specimens with H by heating specimens in H_2 gas (1 atm) followed by quenching. We measured their EPR spectra by an X-band spectrometer at 15 K to determine the concentrations of Cr_i^+ , CrB pair and Cr_s^0 , where the subscripts i and s denote interstitial and substitutional occupation sites, respectively, and superscripts 0 and + denote neutral charge state and positive charge state, respectively.

3. Results and discussion

3.1. Solubility of Cr_i

Fig. 1 shows EPR spectra due to Cr_i^+ before (dashed line) and after (solid line) H-doping. The doping temperature was 1250°C. The EPR intensity due to Cr_i^+ was much reduced due to H-doping. To systematically study this reduction, we performed similar experiments after doping at various temperatures. Fig. 2 shows the results. As clearly seen, the apparent heat of solution, which corresponds to the slope of Fig. 2, decreases much due to H-doping. The apparent heat of solution determined from Fig. 2 were 2.9 ± 0.1 and 1.7 ± 0.1 eV for specimens without and with H-doping, respectively. The former agrees well to the reported data [4].

As for the origin of solubility reduction, we discuss three possibilities; out-diffusion of Cr during H-doping, formation of complexes of Cr and H during H-doping or during quenching and change of occupation sites from interstitial to substitutional sites during quenching. First, we estimated amount of out-diffusion with the use of diffusion data. It was too small to explain the observed results. Second, Sadoh et al. determined the energy levels due to CrH complexes by means of the

DLTS method [5]. We, however, did not observe any extra signal other than Cr_i^+ . We tentatively propose that the reduction of Cr_i solubility occurs due to change of occupation sites from interstitial to substitutional sites during quenching. For the site change to occur, vacancies are necessary. As shown in a separate paper [6], the concentration of vacancy in the form of complexes of vacancies and hydrogen atoms is high when hydrogen is doped. Hence, there is a high probability to change occupation sites during quenching.

3.2. Annealing experiments

In the case of Si co-doped with Fe and H, we observed the formation of Fe–H pairs due to annealing [3]. We studied the isochronal annealing behavior of Cr_i^+ . Fig. 3 shows the result. Circles and dashed line, which was drawn to guide the eye, show the annealing behaviors in the specimen without H-doping. Cr–B pairs were formed around 125°C corresponding to the decrease of Cr_i^+ . At above about 275°C, the intensity of Cr_i^+ decreased. On the other hand, decrease of Cr_i^+ occurred at $> 175^\circ\text{C}$ in the case of H-doped specimen, as shown by triangles and solid line, which was drawn to guide the eye. Hence, these results strongly suggest that diffusion rate of Cr_i^+ is faster in H-doped specimen.

To determine the migration energy of Cr_i^+ , we performed isothermal annealing experiments. Fig. 4 shows the formation of CrB pair due to isothermal annealings at various temperatures in specimens without H-doping. Solid lines are fitting curves due to the first order reaction. Fittings are good. The inset of Fig. 4 shows the dependence of time constant on the annealing temperature. From this inset, the activation energy

Fig. 1. EPR spectra of Cr_i^+ before (dashed line) and after (solid line) H-doping. Cr and H were doped at 1250°C.

Fig. 2. The dependences of EPR intensity on the doping temperature. Cr and H were doped at the same temperatures.

Fig. 3. Isochronal annealing curves of Cr_i^+ in Si without H-doping (circles and dashed line) and with H-doping (triangles and solid line). Annealing duration was 30 min at each temperature.

Fig. 4. Isothermal annealing curves for CrB formation in Si without H-doping. Solid lines were fitting curves due to the first-order reaction. Annealing temperatures of squares, inverse triangles, triangles and circles were 70°C, 80°C, 90°C and 100°C, respectively. The inset shows the dependence of the time constant on the annealing temperature.

Fig. 5. Isothermal annealing curves of Cr_i in Si doped with H. Solid lines were fitting curves due to the first-order reaction. Annealing temperatures of triangles, circles and squares were 210°C, 220°C and 230°C, respectively. The inset shows the dependence of the time constant on the annealing temperature.

for the migration of Cr_i^+ was determined to be $0.95 \pm 0.02 \text{ eV}$, which is in good agreement with the values reported so far (around 1.0 eV) [7]. We also performed isothermal annealing experiment of H-doped specimens. Fig. 5 shows the experimental results and fitting curves with the first order reaction. The inset shows the dependence of the time constant on the annealing temperature. The activation energy of Cr_i^+ diffusion was determined to be $0.70 \pm 0.09 \text{ eV}$, which is smaller than the above value. Hence, there is a reduction of activation energy of Cr_i^+ diffusion due to H doping. Such reduction due to H-doping was first reported for the activation energy of oxygen diffusion in Si [8]. We do not have any explanation for the reduction in the case of Cr. It may be the same in the case of oxygen [9].

Fig. 6. Isochronal annealing curves of Cr_i in a specimen codoped with Cu and Cr. The concentration of Cu was about $1 \times 10^{18} \text{ cm}^{-3}$. AQ denotes the as-quenched state.

According to literatures on Cr_i diffusion [7], the activation energy determined at high temperature is about 1 eV and that determined at low temperature is about 0.8 eV [10,11]. Based on our results, we interpreted smaller activation energy at low temperature to be due to the effect of H since it was determined with the DLTS method. In this method, specimens should be etched to fabricate good Schottky contact. Hydrogen atoms probably come into Si crystals during etching and enhance the Cr_i diffusion.

In Section 3.1, we propose the site change of Cr during quenching. To confirm the site change, we performed annealing experiments of specimens codoped with Cu and Cr. Fig. 6 shows an isochronal annealing curve. The concentration of Cr_s increased at around 300°C and decreased at around 550°C. Hence, Cr_s is more stable than Cr_i . The activation energy for the increase of Cr_s was determined to be about $1.00 \pm 0.07 \text{ eV}$, which is in good agreement with Cr_i diffusion. Hence, the site change is thought to occur due to Cr_i diffusion to vacancies, which are not in isolated state but in a state of complexes.

4. Summary

We studied the properties of Cr in Si doped with H by means of the EPR method. The heat of solution of Cr in H-doped specimens was determined to be $1.7 \pm 0.1 \text{ eV}$, which is much smaller than that ($2.9 \pm 0.1 \text{ eV}$) without H-doping. The activation energy of Cr migration in H-doped specimens was determined to be $0.70 \pm 0.09 \text{ eV}$, which is smaller than that (about 1.0 eV) without H-doping.

Optical absorption spectra of platinum-related defects in silicon

N. Fukata*, K. Saito, M. Suezawa

Institute for Materials Research, Tohoku University, Sendai 980-8577, Japan

Abstract

We studied optical absorption spectra of platinum (Pt)-doped Si and found new optical absorption peaks related to Pt. FZ-Si was separately doped with Pt and H by heating at 1300°C followed by quenching in water. Optical absorption spectra were measured at about 7 K with a Fourier transform infrared spectrometer. We observed a new peak at 1719.4 cm^{-1} in as-quenched specimens and also new peaks in the region from 1300 to 1500 cm^{-1} after annealing at above 500°C. From the isotope shift caused by deuterium doping, the dependence on excitation energy and the annealing behaviors, these peaks were found to be due to the electronic transition of Pt-related defects such as Pt clusters, rather than to the local vibrational modes of H. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Platinum; Hydrogen; Optical absorption; Silicon

1. Introduction

The characteristics of platinum (Pt) in Si have been extensively investigated to control the minority-carrier lifetime, which depends on its energy levels and thermal capture cross sections. There are several Pt-related defects which introduce deep levels in the band gap. The existence of isolated substitutional Pt [1–3], Pt pairs [4,5], 6-Pt clusters [6], Pt–hydrogen (H) complexes [7] and Pt–oxygen complexes [8,9] have so far been reported by studies using electron paramagnetic resonance (EPR) methods, deep level transient spectroscopy (DLTS), and optical absorption spectroscopy. To control the minority-carrier lifetime in fast-switching diodes, it is necessary to understand the properties of the above-mentioned defects, especially, defects introducing the midgap level. In this study, we investigated Pt-related defects in Si from the measurements of their optical absorption since optical absorption measurements have been shown in only a few reports. The formation of Pt-related defects was investigated in a wide temperature range and we found new optical absorption peaks due to

Pt-related defects. The characteristics and constituents of the Pt-related defects were investigated based on the annealing behaviors, isotope shift, and the dependence on excitation energy.

2. Experimental

We used high-purity n-type Si ($[P] = 4 \times 10^{12}\text{ cm}^{-3}$) with a size of about $6 \times 6 \times 12\text{ mm}^3$. To dope Si with Pt, specimens deposited with thin Pt films (40 nm in thickness on the opposite two wide surfaces) were sealed in quartz capsules together with Ar gas and heated at 1300°C for 8 h followed by quenching in water. The solubility of Pt is about 10^{17} cm^{-3} at 1300°C [10]. After Pt doping, the specimens were etched with a mixed acid to remove excess Pt from the surface since Pt tends to form silicide on the specimen surface. To dope Si with H (D), the specimens were then sealed in quartz capsules together with H_2 (D_2) gas and heated at 1300°C for 2 h followed by quenching in water. Detailed explanations of quenching conditions have been reported elsewhere [11,12].

Optical absorption spectra were measured at about 7 K with a Fourier transform infrared (FT-IR)

spectrometer. The spectral resolution was 0.25 cm^{-1} . Low pass filters with cut-off energies of 0.328, 0.403, and 0.670 eV were used in FT-IR measurements to investigate the dependence of optical absorption peaks on excitation energy. Isochronal annealing was carried out for 30 min at each temperature in the range from 100°C to 800°C at 50°C intervals.

3. Results and discussion

In addition to the localized vibrational modes of H in a PtH_2 complex [5] at 1873.0 and 1891.8 cm^{-1} in an as-quenched specimen, we observed a new optical absorption peak at 1719.4 cm^{-1} as shown in Fig. 1. As for the strongest peak observed at 1880.8 cm^{-1} , based on their experiment on the isotope shift, Uftring et al. [7] have suggested that the number of H atoms included in the complex is one, although the detailed structure was not shown in their report. In our study, this peak was observed only in specimens doped with Pt and H. In a D-doped specimen, the 1880.8 cm^{-1} peak was shifted to 1358.5 cm^{-1} . In a specimen co-doped with H and D, no splitting of the 1880.8 (1358.5) cm^{-1} peak was observed. These results indicate that the 1880.8 cm^{-1} peak is due to the localized vibrational modes of H and that the number of H atoms included in the complex is one, the same conclusion as that of Uftring et al. [7]. The intensity of the 1880.8 cm^{-1} peak was higher than those of the 1873.0 and 1891.8 cm^{-1} peaks which are due to the PtH_2 complex. This result means that the complex responsible for the 1880.8 cm^{-1} peak is formed more easily than the PtH_2 complex during quenching. In the as-quenched specimen, almost all Pt atoms exist not in pairs or clusters but in isolated Pt or Pt–H complexes since the quenching speed is high enough to quench Pt

atoms [11]. Considering all these results, the 1880.8 cm^{-1} peak is probably due to the localized vibrational modes of H in the PtH complex.

Fig. 1 also shows the annealing behavior of optical absorption peaks observed in this study. With increasing annealing temperature, the intensity of the new 1719.4 cm^{-1} peak increases, in contrast with the decrease in intensity of the peaks due to the PtH_2 and PtH complexes. After annealing at above 500°C , we observed new peaks in the range of 1300 – 1500 cm^{-1} , which were not observed by Uftring et al. These peak positions changed with the annealing temperature. After annealing at 800°C , at least four peaks were observed at about 1301 , 1318 , 1452 and 1474 cm^{-1} as shown in Fig. 3. These five new peaks showed similar annealing behavior. These new peaks were also observed in a specimen doped with Pt only and did not shift as a result of D doping. Thus these new peaks are not due to the localized vibrational modes of H. Considering these results, these new peaks are probably due to electronic transitions associated with defect centers including Pt only.

Next, we investigated the dependence of these new peaks on the cut-off energy by placing a low pass filter between the specimen and the light source of FT-IR equipment. The intensities of these peaks changed depending on the cut-off energy of the low pass filters as shown in Fig. 2. This result suggests that these peaks are due to the electronic transition of Pt-related defects. Fig. 2 also shows another interesting result. There is an anticorrelation between the intensity of 1719.4 cm^{-1} peak and those of the other four peaks observed at about 1301 , 1318 , 1452 , and 1474 cm^{-1} . The intensity of the 1719.4 cm^{-1} peak increases with decreasing cut-off energy. In the case of the latter four peaks, the intensities decrease with decreasing cut-off energy. These latter four peaks showed the same dependence on excitation energy. Peak intensities increased monotonically with

Fig. 1. Optical absorption spectra observed in Pt-doped Si (a) before and after annealing at (b) 500°C , (c) 600°C , and (d) 800°C . Deconvolutions of the optical absorption spectrum are added to the spectrum observed after annealing at 800°C .

Fig. 2. Optical absorption spectra observed in Pt-doped Si (a) without and with low-pass filters of (b) 0.7 eV , (c) 0.403 eV , and (d) 0.328 eV .

excitation energy and were close to those without a low pass filter when a 0.670 eV-filter was used. It is thus indicated that the defect centers which give rise to the optical absorption at about 1301, 1318, 1452, and 1474 cm^{-1} become IR-active centers by illumination. This dependence on excitation energy, i.e., monotonic dependence without any peaks, suggests that excitation occurs between a localized state in the band gap and extended states.

Considering the annealing behaviors and the dependence on excitation energy of these new peaks, are probably due to the same Pt-related defect. The 1719.4 cm^{-1} peak intensity in p-type silicon was much greater than that in n-type silicon. Based on these results, these new peaks are probably due to hole transitions. Detailed explanations will be shown elsewhere. To determine the optical threshold energy of the excitation of these defect centers, we analyzed the data using Lucovsky's model, which gives the optical cross section for electronic transitions between a localized state and a band [13,14]. In this analysis, we assumed that the energy of illumination was the cut-off energy for each low pass filter since the highest energy had the strongest effect. Considering this, the optical cross section (σ) can be written as

$$\sigma = \sigma_0 \{ [4E_D(h\nu - E_D)] / (h\nu)^2 \}^{3/2}, \quad (1)$$

where E_D is the optical threshold energy and $h\nu$ is the photon energy. Eq. (2) is deduced from Eq. (1),

$$Y^{2/3} X^2 = 4E_D(X - E_D), \quad (2)$$

where $Y = \sigma/\sigma_0$, $X = h\nu$. In this experiment, σ/σ_0 is I/I_0 , where I and I_0 are the intensities of the optical absorption peak observed in experiments with and without a low-pass filter. Fig. 3 shows the relation between $Y^{2/3} X^2$ and X . They have a linear relation and

Fig. 3. Fitting of the excitation spectrum with Lucovsky's model. The closed circles (●) and the closed triangles (▲) are the data of the 1301 and 1318 cm^{-1} peaks and 1452 and 1474 cm^{-1} peaks, respectively.

we obtained an optical threshold energy of about 0.34 eV.

These new defects are formed by annealing. This fact shows that these new centers are probably not due to isolated Pt but rather to Pt clusters. According to Höhne et al. [6] 6-Pt clusters were formed by subsequent annealing at 540°C after indiffusion of Pt at 1200°C. The formation temperature of the new peaks observed in this study is close to that of 6-Pt clusters. In this study, Pt doping was performed at 1300°C where the solubility of Pt in Si is about 10^{17}cm^{-3} . Pt atoms introduced at 1300°C are supersaturated during annealing at below 1300°C and therefore probably form clusters by annealing at 800°C where the diffusion length of Pt atoms is on the order of 10^{-6}cm [15]. After annealing at 800°C, we heated the specimen again at 1000°C for 1 h and annealed it at 800°C for 30 min. The intensities of the peaks observed in the region from 1300 to 1720 cm^{-1} decreased up to about 70% of those before. This decrease of the intensity is probably due to the precipitation of Pt atoms since heating at 1000°C precipitates Pt atoms introduced at 1300°C and therefore the new peaks do not come from the precipitates of Pt. Based on these considerations, the peaks observed in the region from 1300 to 1720 cm^{-1} are probably due to Pt clusters.

4. Conclusions

We observed a new optical absorption peak at 1719.4 cm^{-1} in as-quenched specimens in addition to the peaks due to the PtH_2 and the PtH , and new peaks in the range of 1300–1500 cm^{-1} after subsequent annealing at above 500°C. The optical threshold energy of the defects attributed to 1300–1450 cm^{-1} peaks was determined to be about 0.34 eV by applying Lucovsky's model. From the isotope shift by D-doping, the dependence on excitation energy, and the annealing behaviors, these peaks were found to be due to the electronic transition of Pt-related defects such as Pt clusters.

Abstract

A strong gettering effect appears after high-energy Si self-implantation and subsequent annealing in two zones at the projected range of the silicon ions (R_p) and in a region at about $R_p/2$. The defects responsible for the impurity gettering at $R_p/2$ were studied by means of positron annihilation. It was found that diffusing Cu impurities were captured by small vacancy agglomerates. Monoenergetic positron beams with improved depth resolution were used to characterize the defects. Excellent depth resolution was obtained when samples were wedge-shaped polished and studied using the Munich Scanning Positron Microscope. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Self-implantation; Gettering; $R_p/2$; Positron annihilation

1. Introduction

Impurity gettering in silicon is a major problem in semiconductor device fabrication particularly when the dimensions of the components shrink. After high-energy self-implantation and subsequent annealing, two getter zones were found by SIMS measurements after intentional impurity contamination [1,2]. The deeper zone is located at R_p (projected range of implanted Si ions). A network of interstitial-type dislocation loops are responsible for the gettering effect at R_p (found by TEM). A second pronounced getter zone is observed in the $R_p/2$ region (between surface and R_p). No extended defects were found in this zone by TEM. A controversial discussion about the nature of this defects have recently be overcome, and it is now widely accepted that open-volume defects are responsible for the gettering effect at $R_p/2$.

Positron annihilation spectroscopy is a unique tool to study open-volume defects in semiconductors [3]. Especially the technique variable energy positron annihilation spectroscopy (VEPAS) seems to be promising for the study of $R_p/2$. Here, the penetration depth of positrons and thus the information depth of the method can be controlled by the acceleration voltage of a monoenergetic positron beam. However, at higher positron energies (> 10 keV) the penetration profile becomes rather broad, so that buried defect layers in a depth of several microns can hardly be studied. Thus, an improvement of the depth resolution is necessary in order to treat the $R_p/2$ effect by positrons. In an earlier study [4], we removed the sample surface layer by layer by ion sputtering in order to obtain the optimum depth resolution for the VEPAS experiment. In this paper we present for the first time the use of a positron microscope for defect depth profiling.

2. Experimental details

Cz-silicon wafers were implanted by 3.5 MeV Si^+ (dose: $5 \times 10^{15} \text{ cm}^{-2}$). One sample was co-implanted

The lower panel shows the Cu depth profile obtained by SIMS.

with 4 MeV P^+ and a dose of $1 \times 10^{15} \text{ cm}^{-2}$ (sample in Fig. 1). For all samples, a rapid-thermal annealing (RTA) step (30 s at 900°C) was performed after implantation, followed by a Cu contamination of the sample (Cu^+ implantation into the backside of the sample, 20 keV, $1 \times 10^{13} \text{ Cu}^+ \text{ cm}^{-2}$). A further annealing step under Ar atmosphere (3 min at 700°C) was performed to realize the Cu diffusion. The VEPAS experiments presented in Figs. 1 and 2 were performed using a magnetically guided continuous positron beam system (for experimental details see Ref. [4]). The stepwise removal of the sample in Fig. 1 was realized by Ar^+ sputtering (2 kV, 10^{-6} mbar, 40 μA , 30 min, 60°, etching rate 3.4 nm/min). Special attention was paid to ensure that the defects created during sputtering in a thin surface layer are not affecting the defect detection in the sample region under observation. This was proved in a reference Si sample which did not show any positron traps after a removal of 200 nm by sputtering. The surface of the sample in Fig. 3 was polished in a wedge shape with a flat angle of 0.81°. This wedge was studied with the Munich Scanning Positron Microscope [5] with a constant positron incident energy of 8 keV, a lateral resolution of about 10 μm , and a time resolution of the positron lifetime measurement of about 250 ps. In order to obtain the defect depth scan, the positron lifetime spectrum was measured at 45 points each separated by

Fig. 2. Doppler broadening VEPAS measurement of self-implanted Si (3.5 MeV, $5 \times 10^{15} \text{ cm}^{-2}$, annealed 30 s at 900°C). A set of samples was additionally implanted by Si^+ ions into the $R_p/2$ region with increasing dose (indicated in the figure). Thereafter, the samples were chemically etched by 1.2 μm in order to obtain maximum sensitivity in the $R_p/2$ range with a conventional slow-positron beam.

Fig. 3. Defect depth profile of a self-implanted Si sample (3.5 MeV, $5 \times 10^{15} \text{ cm}^{-2}$, annealed 30 s at 900°C, Cu contaminated) using the Munich Scanning Positron Microscope. The sample surface was wedge-shaped polished. The profile was then taken as a line scan along the wedge with constant positron energy of 8 keV. Each positron lifetime measurement is separated by 11 μm corresponding to a depth difference of 155 nm. The depth scale was calculated according to the wedge angle of 0.81°, and the mean positron implantation depth of 400 nm was added.

about 11 μm along the wedge. Thus, the depth difference between the individual measurements corresponds to about 155 nm which is distinctly smaller than the mean positron penetration depth at 8 keV. This is in silicon about 400 nm which gives therefore the depth resolution of the experiment. In contrast to conventional VEPAS, this resolution is constant for the whole depth range. The incident energy cannot be decreased in order to obtain a better depth resolution because the fraction of positrons which diffuse back to the surface would become too large.

3. Results and discussion

Fig. 1 shows the results of the defect depth scan after implantation, annealing, and Cu contamination [4]. The lower panel shows the Cu profile obtained by a SIMS depth scan. The gettering zones at $R_p/2$ and R_p are well visible. The upper panel presents the result of the VEPAS doppler-broadening measurement. The depth scan was obtained by successively sputtering the sample surface. The S parameter shows two pronounced peaks at $R_p/2$ and R_p , clearly indicating the presence of open-volume defects in both regions. In the R_p region, the W parameter is smaller than W_{bulk} . This is the expected behavior in case of positron trapping by vacancy-type defects. However, in the $R_p/2$ region, in addition to the S parameter, also the W parameter increases distinctly above the bulk value. This finding can only be understood when assuming that the open-volume defect is not entirely surrounded by silicon. Thus, it must be concluded that Cu atoms are built in the boundary of the vacancy-type defect in the $R_p/2$ region. On the other hand, this is not observed in the R_p region, where the gettering centers are obviously different from the positron trapping centers. From this results, additional Doppler-broadening coincidence measurements, and a study using the Munich Slow-positron Lifetime Beam it was concluded that small vacancy clusters capture the diffusing impurities at $R_p/2$ and divacancy-type defects probably bound to the interstitial-type dislocation loops are detected at R_p [4].

The first conclusion is supported by the following experiment: a set of high-energy self-implanted Si samples (3.5 MeV, $5 \times 10^{15} \text{ cm}^{-2}$, annealed 30 s at 900°C) was additionally implanted by Si^+ ions with increasing dose into the $R_p/2$ region (energy was chosen to have the projected range of the post-implanted Si^+ ions in the $R_p/2$ region of the high-energy implantation). The samples were then chemically etched by 1.2 μm in order to use a conventional slow-positron beam to study the $R_p/2$ region (Fig. 2). The upper curve (no post-implantation) exhibits a distinct increase compared to the defect-free reference sample due to positron trapping by vacancy agglomerates. The additional implantation

with a dose of $2 \times 10^{14} \text{ cm}^{-2}$ distinctly decreases the effect. Obviously, open-volume defects formed during high-energy self-implantation are partly filled by the implanted excess Si interstitials of the post-implantation. However, with increasing dose, the S parameter increases again due to the increasing number of open-volume defects created by the additional implantation.

The improvement of the depth resolution by stepwise ion sputtering of the sample makes it possible to show the defect profiles in a larger depth, e.g. at R_p . However, the experiment needs a long time (several days). Moreover, the sputtering is not completely homogeneous. Thus, after long-term etching the surface is not smooth any more. Another problem appears in a compound semiconductor due to selective sputtering. These drawbacks can be avoided by using a focused positron beam and a wedge-shaped sample. Fig. 3 shows the first result of this type of defect depth profiling. We used the Munich Scanning Positron Microscope to measure the defect profile in a high-energy self-implanted Si sample (3.5 MeV, $5 \times 10^{15} \text{ cm}^{-2}$, annealed 30 s at 900°C, Cu contaminated). A wedge of 0.81° was prepared by a polishing technique, which is used for spreading resistance measurements. In a reference experiment using a Si sample in as-grown state it was shown that the grinding defects only alter the surface annihilation parameters, but do not penetrate more than 100 nm into the sample.

The high quality of the obtained defect profile is obvious. Both defect zones which were found in Fig. 1 can also be seen. In the $R_p/2$ region, the defect-related lifetime is 450 ps thus indicating the existence of small vacancy clusters ($n \geq 10$). The cluster density increases to a depth of 1.8 μm . Around a depth of 2 μm , the cluster signal disappears, and a defect becomes detectable with an open volume comparable to a divacancy ($\tau_2 \approx 330$ ps). The fraction of trapped positrons is rather high. Since excess divacancies anneal below 370°C [6], the observed defects must be stabilized or being part of the dislocation loops present in this region. The positron lifetime of the bulk region ($> 3 \mu\text{m}$) is about 270 ps and thus distinctly larger than the lifetime of defect-free Si (218 ps). Due to the lack of defects, a distinct fraction of positrons (about 30%) diffuse back to the surface annihilating there at the surface or in the thin defect-rich surface layer remaining after mechanical polishing. However, in the R_p and $R_p/2$ region, the positron diffusion length is expected to be smaller than 100 nm, so that the influence of the surface can be neglected.

4. Conclusions

It can be concluded that the two methods of depth-resolution enhanced VEPAS enabled us to identify

different vacancy-type defects in high-energy self-implanted Si. In the $R_p/2$ region point defect clusters containing vacancy-type defects were undoubtedly found. Diffusing copper atoms are trapped there and are clearly detected by positrons to be in the direct surrounding of the annihilation site.

Abstract

First direct evidence is given on the formation of dislocations in room-temperature nanoindentation experiments of gallium arsenide wafers. The formation of dislocation loops, which have been examined by transmission electron microscopy, can be related to the pop-in effect found in depth-sensitive hardness measurements. In the case of silicon, no dislocations are found. Instead, different high-pressure phases could be identified by Raman microscopy. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Deformation; Nanoindentation; Dislocation sources; Transmission electron microscopy

1. Introduction

The plastic deformation of semiconductors in the low temperature/high stress region is of particular interest due to the anticipated change in the dislocation motion. It is well accepted that dislocations are dissociated in the glide set and move via the thermal activation and migration of double kinks in a medium range of temperature and stress [1]. However, the calculation of Duesbery and Joós [2] demonstrated for silicon that the motion of perfect dislocations in the shuffle set has a lower activation energy at high stresses. The transition from the motion of dissociated glide set dislocations to the predominance of undissociated shuffle set dislocations is expected at a stress of about $0.01G$ (G shear modulus). It is difficult to extend the deformation experiments to the range of high stresses and low temperatures. One approach is the uniaxial compression under confining pressure. In the case of silicon, it has not been possible to go to deformation temperatures lower than 550 K, even with a confining pressure of 1.5 GPa [3]. The other difficulty is that existing glide set dislocations formed in a pre-deformation stage may

prevent the transition to a deformation mode which is fully controlled by shuffle set dislocations.

The second approach to high-stress deformation is the use of a diamond indenter. Because of its simplicity, nanoindentation is a very popular but still badly understood method for the study of local mechanical properties. In depth-sensitive hardness measurements, a sudden jump in the displacement may occur at a certain load. This finding is referred to as the pop-in effect. In this paper, we report on nanoindentation experiments and the investigation of the defect structure produced by the local deformation in GaAs and Si wafers.

2. Experimental details

The MTS Corp. Nanoindenter II was used for depth-sensitive hardness measurements. As measured by atomic force microscopy, the tip of the Vickers indenter used can be regarded as a sphere with a tip radius of about 1 μm . We investigated the force versus displacement curves during the penetration of the diamond tip in polished (001) and (111) surfaces of undoped liquid encapsulated Czochralski-grown GaAs wafers (supplied by Freiburger Compound Materials). Additionally, float zone (001) silicon wafers (Wacker) were studied. In order to investigate the defect structure at the indentations, the samples were indented at room temperature in

Fig. 1. Force versus penetration depth for a nanoindentation experiment on a polished (001)-oriented GaAs wafer. The discontinuity in the curve at the force of about 45 mN is referred to as the pop-in effect. The upper branch corresponds to the loading, the lower one to the unloading of the diamond tip. The lines are to guide the eye.

an array of 40×30 identical indents. The extension of the whole array was $780 \times 580 \mu\text{m}^2$. A maximum load of 0.550 mN has been chosen, because this value is close to the critical force of the pop-in effect occurring at 45 mN (Fig. 1). In this way, the state immediately after the pop-in could be examined microscopically for several indentations. The loading rate was 0.055 mN/s, the unloading rate 0.400 mN/s. After indentation, the samples were prepared by backside grinding, polishing, and argon ion milling for investigations by transmission electron microscopy (TEM). The TEM examination was carried out using bright-field diffraction contrast in a JEM 1000 microscope operating at 1 MV.

Raman measurements were carried out on impressions with an indenter load of up to 1 N using a Dilor LabRam Raman microscope. The 632.8 nm line of a He–Ne laser with a power of 25 mW was used for Raman scattering.

3. Results and discussion

3.1. Gallium arsenide

The examination of the indentations by TEM shows fourfold dislocation rosettes for (001) and threefold rosettes for (111) GaAs wafers. The dislocations have an extent of up to 200 nm from the indentation center (Fig. 2). Individual dislocation loops outside the tangled rosettes may appear up to a distance of 350 nm. The geometry of the dislocation slip corresponds to the $\{111\}\langle 1\bar{1}0 \rangle$ glide prism model derived for the dislocation patterns around Vickers microindentations produced with higher loads [4,5]. However, in contrast to the more extended rosettes at such indentations, no

Fig. 2. Plan view TEM bright-field images of the dislocation rosettes at nanoindentations in (001) GaAs (a) and (111) GaAs (b). The diffraction vector \mathbf{g} is $2\bar{2}0$.

anisotropy due to different glide velocities of α and β dislocations appeared in our nanoindentation experiment. This may be due to the fact that the usual expression of thermally activated dislocation glide velocity [1],

$$v = B\tau^m \exp\left(-\frac{U}{k_{\text{BT}}}\right)$$

(B constant, τ resolved shear stress, m stress exponent, U activation energy, k_{B} Boltzmann constant, T temperature) cannot account for the extension of the loops in the high-stress regime.

Only perfect dislocation loops with Burgers vectors $\mathbf{b} = \frac{1}{2}\langle 110 \rangle$ could be identified in the TEM images according to the $\mathbf{g} \cdot \mathbf{b} = 0$ extinction rule (\mathbf{g} diffraction vector). No partial dislocations and stacking faults are recognized. TEM tilting experiments have shown that all loops have the Burgers vectors inclined to the surface. There is no indication of the formation of cracks or other phases, so the local deformation seems to proceed

exclusively by the formation and propagation of dislocations.

The dislocation rosettes at nanoindentations investigated by TEM represent the state after the following processes: (i) generation of embryonic dislocation loops giving rise to the pop-in effect, (ii) further plastic deformation via coalescence and expansion of these loops during or immediately after the pop-in, (iii) relaxation and stabilization of the dislocation structure upon unloading. The generation of loops can be understood as homogeneous dislocation nucleation. The elastic self-energy of a dislocation loop with the magnitude of the Burgers vector b and the radius r is given by [6]

$$E_c = \frac{Gb^2r}{4} \frac{2-\nu}{1-\nu} \left(\ln \frac{4r}{r_0} - 2 \right),$$

where ν is Poisson's ratio and r_0 the cutoff radius at the dislocation core. The strain energy released by the formation of the loop under the action of the resolved shear stress τ is

$$E_\tau = -\tau b \pi r^2.$$

Maximizing the total energy $E_c + E_\tau$ provides the critical radius r_c and the maximum free energy E_c of the loop formed. For 0 K ($E_c = 0$), the critical stress of dislocation nucleation is obtained as

$$\tau_c = \frac{Gb}{\pi e^3 r_0} \frac{2-\nu}{1-\nu}, \quad (1)$$

where e is the Euler number. With typical values of $r_0 = b/3$ and $\nu = 0.312$ for GaAs, we get $r_c \approx 0.7$ nm and $\tau_c \approx G/9 = 6$ GPa.

During depth-sensitive hardness measurements, the diamond indenter sphere is driven into the sample under continuous monitoring of load and penetration depth. In the indentation experiment, the maximum shear stress τ_T (Tresca stress) is directly proportional to the mean contact pressure p_m . It can be expressed with the effective Young's modulus E by the indenter radius and the penetration depth h , as it follows from the Hertzian contact theory of a hard sphere [7],

$$\tau_T = 0.465 p_m = 0.197 E \sqrt{\frac{h}{R}}.$$

Depending on the actual values of the penetration depth and the indenter radius R , the Tresca stress can be as high as 10 GPa. According to the calculations of dislocation theory given above, this amount of stress is sufficient for homogeneous dislocation nucleation in GaAs.

The number of loops formed can be estimated from the work done during the pop-in (critical force times the displacement). From the shaded area in Fig. 1, this work is obtained as 1.7×10^{-12} Nm. If this work is related to the energy of a critical-sized loop $E_c(r_c)$, we obtain that

5×10^4 loops must have been formed. A higher number of 1.3×10^6 loops is obtained when the total dissipation energy, as the area between the loading and the unloading curves (Fig. 1), is related to $E_c(r_c)$. Such an estimation provides the upper limit of the number of loops with a critical size in the nascent state, when it is assumed that the whole energy input by the indentation is transferred into the formation of dislocations. The number of extended loops found in the TEM images at one indentation site is not higher than 100. Eq. (1) represents the upper limit of the shear stress at 0 K. At higher temperatures, the thermal contribution lowers the shear stress and the critical radius becomes higher. After their formation, the embryonic loops grow further and coalesce under the action of the applied load. The unloading may give rise to a small relaxation of the dislocation structure, but the residual strain of the indent finally stabilizes the dislocation rosette pattern.

3.2. Silicon

The substructure around indentations in Si is completely different to that of GaAs. Despite the fact that a pop-in effect also occurs, no dislocations could be found. Only a high number of small cracks, which also appear at the surface (see the inset of Fig. 3), could be identified. The indentation stress is high enough to cause phase transitions in Si, which have been extensively studied by Kailer et al. [8]. In contrast to GaAs, the critical shear stress τ_c for the generation of dislocations in silicon is higher than that for the onset of phase transitions. The actual phases formed depend strongly on the indentation conditions, such as dwell time, loading, and unloading rate. Larger Vickers indentations produced

Fig. 3. Room temperature Raman spectra taken in the deformed region of a microindentation in silicon. The bands at 521 cm^{-1} are due to silicon with diamond structure (Si-I), hexagonal nanocrystalline Si (Si-IV), and amorphous Si (a-Si) [8]. The inset shows a secondary electron image of an indentation taken in a scanning electron microscope.

with higher loads extend to several micrometers. They have been examined by Raman microscopy. The result is shown in Fig. 3. The spectra taken in different positions of the indent distinctly differ. In the case of fast unloading (Fig. 3), bands due to amorphous and hexagonal Si could be identified in addition to the low pressure diamond structure.

4. Conclusions

In the case of silicon, different high-pressures phases could be identified by Raman microscopy. The occurrence of the different phases strongly depends on the indentation load and the loading/unloading rate. In contrast to Si, there are no indications of phase transitions in the case of GaAs. Instead, the pop-in effect in GaAs can be related to the formation of dislocation loops. First direct evidence by transmission electron microscopy is given on the formation of dislocations in room-temperature nanoindentation experiments of gallium arsenide. The number of loops generated have been estimated from energetical considerations and compared to the number found in TEM. Only perfect dislocation loops could be identified in the TEM images. These results are in agreement with the

motion of non-dissociated shuffle-set dislocations, which are supposed to occur in the low temperature/high stress deformation regime.

Mechanical strength of nitrogen-doped silicon single crystal investigated by three-point bending method

G. Wang, D. Yang*, D. Li, Q. Shui, J. Yang, D. Que

State Key Lab of Silicon Materials, Zhejiang University, Hangzhou 310027, People's Republic of China

Abstract

The mechanical strength of nitrogen-doped Czochralski silicon (NCZ-Si) and conventional Czochralski silicon (CZ-Si) have been investigated by three-point bending method at room temperature. It was found that the mechanical strength of silicon had been increased markedly at room temperature due to the doping of nitrogen. The effects of the surface condition and the orientation of silicon crystal on mechanical strength were determined. The mechanism of the mechanical strength increased by nitrogen in silicon is also discussed. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Mechanical strength; Nitrogen; Silicon

1. Introduction

With the development of the large-scale integrated circuit (IC) and the increasing of the silicon wafer's diameter, it is important to improve the mechanical strength of silicon material and to diminish the warpage of silicon wafers. Moreover, the mechanical properties of silicon at room temperature often dictate fundamental limits on the fabrication and packaging of modern semiconductor devices, but less research was done [1–4].

However, the plasticity of silicon crystal has been extensively studied. Except for the intrinsic property, the surface condition of samples and the doped impurities were the important factors that influenced the strength of silicon. Sumino et al. [5] found that damage on the surface had great effect on silicon's mechanical strength at high temperatures. Impurities also have great effect on the mechanical strength of silicon at high temperature [6–11]. It was reported that the interstitial oxygen enhanced the tensile stress and pinned efficiently the movement of dislocations [6–8]. However, the pinning

effect of nitrogen on the mechanical property of silicon was much stronger than that of oxygen at high temperatures [9–11]. Moreover, the study of the mechanical property of silicon at room temperature is relatively scarcer. Chen et al. found by fracture that the different orientations of single crystal silicon had different mechanical strengths [1]. It was suggested that the fracture path depended not only on the level of resistance but also on the change of fracture energy with orientation [1,2]. Besides the intrinsic anisotropy mentioned above, the different extrinsic strength-limiting flaws and strength distributions would be operative depending on the manner in which a silicon component was stressed [2,3]. Also there is a theoretical computation that impurities would influence the fracture and ideal tensile strength of silicon crystal [12,13]. However, the influence of impurities on fracture process and fracture strength was seldom given attention.

In this paper, we measured the mechanical strength of CZ silicon and NCZ silicon by means of three-point bending at room temperature. The effects of surface condition and the orientation of samples on the mechanical strength were detected. The influence of nitrogen in silicon crystal was also discussed.

2. Experiment

Three inch, 40 Ω cm CZ silicon wafers with $\langle 111 \rangle$ orientation were used in our experiments. NCZ-Si and CZ-Si were grown under almost the same conditions, except for the protection atmosphere. The concentration of impurities was measured at room temperature by a Nicolet Impact410 Fourier transmission Infrared Spectroscope (FTIR) as shown in Table 1.

The wafers with the orientation of $\langle 111 \rangle$ and $\langle 110 \rangle$ were cut into bars with the dimension of $25 \times 5 \times 5 \text{ mm}^3$. Then the bars were divided into five groups. There were about four or five specimens in each group. In order to compare the influence of flaws on the surface of samples, two steps of pretreatment mechanical grinding were carried out. Groups 1 and 2 were only ground with Al_2O_3 . Groups 3–5 were mechanically polished by diamond grinding creams after Al_2O_3 grinding. All the groups after mechanical grinding and polishing were etched about 5 min in $\text{HF}:\text{HNO}_3=1:3$ (volume) etchant to remove surface damage. Finally, the mechanical strength of the samples was measured by three-point bending technique with a DKZ-5000 dynamoelectric bending machine at room temperature. The sample surface loaded forces were $\langle 111 \rangle$ and $\langle 110 \rangle$, respectively. According to the maximum compressive stress, the fracture strength is given by the following formula:

$$\sigma = \frac{3PL}{2BH^2},$$

where σ is the maximum compressive stress of bars, P is the loaded force, B , H and L ($L = 20 \text{ mm}$) are the width, height and length of pressing-groove, respectively.

3. Results and discussion

The fracture strength of CZ and NCZ silicon samples with different orientations are given in Table 2. It can be seen from Table 2 that for both CZ and NCZ silicon, the polishing pretreatment increased the fracture strength σ in comparison with only the grinding pretreatment. The fracture strength of NCZ silicon with $\langle 111 \rangle$ orientation was higher than that of CZ silicon after both grinding and polishing pretreatment. Furthermore, the fracture strength of the CZ silicon with $\langle 110 \rangle$ orientation was higher than that with $\langle 111 \rangle$ orientation.

It was found in our experiment that the initial crack appeared in the central position of the back surface of samples where the highest tensile stress was produced. Figs. 1(a) and (b) show the scanning electronic microscopy (SEM) photo of the fractal surface of a silicon sample with $\langle 111 \rangle$ orientation and its illustration. The SEM photo indicated that the fractal surface had three parts. The angles between each part were 120° and 70° , respectively. The part 1 was the initial crack part and was parallel to the $\{112\}$ plane. The parts 2 and 3 were considered as the $\{111\}$ planes.

It is well known that single crystal silicon is a brittle material. Its fracture process belongs to the cleavage fracture. The $\{111\}$ plane with the maximum atom density and the highest Young's modulus is the weakest one in which fracture is easy to generate. Tsai and Mecholsky [14] suggested that the fracture planes of $\{110\}$ with the $\{110\}$ and $\{100\}$ tensile surface both initiated on the $\{110\}$ plane and had the tendency to deviate to the $\{111\}$ plane. In one word, the crack generated on the original loading plane and then deviated from that plane to the $\{111\}$ plane. Hereafter, in our experiment, the initial crack plane was in the center of the backside surface where the highest tensile stress was produced. From Figs. 1(a) and (b), it is easy to get that the initial crack path was the $\{112\}$ plane. However, the weakest plane is the $\{111\}$ plane in silicon crystal. Therefore, with the crack path developing, the crack path kinked to the $\{111\}$ plane. Both NCZ-Si and CZ-Si showed the same fracture characteristics. It indicates that NCZ-Si has the same mechanism of fracture as CZ-Si.

Comparing the mechanical strength between the Groups 1 and 3, and Groups 2 and 4, respectively (Table 2), we found that the mechanical strength of smooth surface samples with little defects (polishing pretreatment) was higher than rough-surface ones (grinding pretreatment). It was the same for both CZ-Si and NCZ-Si. It is known that there are three parameters that have the relation to mechanical strength, according to the Griffith formula, as follows:

$$\sigma = \sqrt{\frac{4E\gamma}{\pi c}},$$

where E is the Young's modulus, γ the surface energy, and c the crack length. Generally speaking, Young's modulus is invariable for the same material in the same orientation. The surface energy is related to the

arrangement of atoms. For the same material and the same orientation, E and γ can be considered to be constant. Crack length c is the only factor to affect samples' mechanical strength. In general, grinding could induce a damage layer in the near surface of silicon samples, including a plastic deformation layer and an elastic deformation layer. By polishing, most of the damaged layer will be removed. In our samples, the ground silicon samples and the polished silicon samples were etched for the same time. Therefore, the residual stress in the ground silicon samples could exist while all of the damage in the polished silicon samples was removed by etching. The residual stress may have resulted in crack length which was longer in the ground silicon samples, so that the mechanical strength was lower. On the other hand, the surface roughness of polished samples was less than that of the grinding samples. After etching, the surface of both kinds of samples was still rough. The roughness can be taken as notches, which will lead to the concentration of stress when loaded. The rougher the surface, the deeper the notches were. Thus, the strength of bars would be lower when loaded for the samples with deeper notches. Therefore, from the viewpoint of both the residual

stress and surface roughness, the mechanical strength was surely lower for the grinding samples compared to the polishing samples.

Since single crystal silicon is an anisotropic material, the flexure strength should be different at different orientations. In our experiment, the flexure strength of Group 3 with $\langle 111 \rangle$ orientation and Group 5 with $\langle 110 \rangle$ orientation shows the difference. Although the initial crack appeared with the same $\{112\}$ plane in both groups, the crack path was different. The initial crack lay on the orientation of $\{11\bar{2}\}\langle 111 \rangle$ for the samples with $\langle 111 \rangle$ orientation and $\{11\bar{2}\}\langle 1\bar{1}0 \rangle$ for the samples with $\langle 110 \rangle$ orientation, respectively. As mentioned above, the crack path would develop to $\{111\}$ plane at last. But the initial crack orientation was not the same; the crack path would not be the same. From this viewpoint, the different crack path may be the reason for the different flexure strength for Groups 3 and 5.

However, our results also showed that the flexure strength of NCZ-Si was higher than that of CZ-Si. The reasons may be as below: (1) As nitrogen was doped in NCZ silicon, N–O, N–N and N–Si bonds were formed, which had the higher bond energy than Si–Si bond.

Consequently, more energy was needed in NCZ silicon than in CZ silicon when they were fractured. (2) During the cooling process of crystal growth, a large number of small-diameter and high-density oxygen precipitation cores were nucleated, which increased the dissipation of energy during the process of fracture. Also, the complex of impurities may cause the crack path variant and lead to the different flexure strength. (3) The doping impurities would shift the Fermi level and change the ideal tensile stress as reported [12,13]. Thus, the Shockley surface states produced during the crystal cleaving process (microscopically, double kink nucleation or migration) would influence the flexure strength greatly. The result indicates that nitrogen improves the mechanical strength of single crystal silicon at room temperature, whatever the surfaces of the samples are, rough or smooth if under the same fracture conditions.

4. Conclusions

We studied the flexure strength of single crystal silicon doped with nitrogen (NCZ) and the silicon without nitrogen (CZ) by three-point bending method at room temperature. The result indicates the doped nitrogen increase of the flexure strength of single crystal silicon. It is suggested that the nitrogen atom in silicon formed the bonds with silicon atom and oxygen atom, which improves the single crystal silicon's mechanical strength. Besides, nitrogen in silicon helped the formation of oxygen precipitation, which pins the dislocations in the process of fracture, leading to higher flexure strength. The surface condition of silicon has a great effect on its mechanical strength. The crack quantity and length on

the surface are the main factors. Different orientation plane is another factor to affect the mechanical strength, due to the different crack path.

Abstract

Although there have been made many calculations for structures of the self-interstitial in Si and small aggregates of interstitials, I_n , there have been relatively few attempts to relate these defects with experimental data. Here, we discuss the assignments of the self-interstitial to the AA12 EPR centre and the di-interstitial to the P6 EPR centre. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Interstitials; AA12; P6; Ab initio theory

1. Introduction

Recently, the AA12 electron paramagnetic resonance (EPR) centre has been assigned to the self-interstitial in Si trapped at a tetrahedral site [1]. AA12 is an isotropic centre with a resolved 45 MHz hyperfine interaction with a single Si atom. Unresolved hyperfine interactions with shells of 4–6 Si atoms have also been detected. The small value of the hyperfine tensor suggests that only 1.5% of the spin density is localised in an s-orbital on the interstitial. The spectrum is found when p-Si is irradiated with 30 MeV protons (or 4.7 MeV α -particles) between 77 and 270 K, and subsequently the sample is illuminated with band gap light. The defect has been correlated with a minority carrier transient spectroscopy (MCTS) level at $E_c - 0.39$ eV and anneals at 350 K in the dark or at 77 K under minority carrier injection. The growth of other interstitial defects, such as C_i , Al_i and Si_i-O_i , is detected after the anneal. The implication is that the (+/+ +) level of I_1 lies at $E_c -$

0.39 eV and the defect is unstable when neutral. It seems strange that the defect is created in high energy proton irradiation as low energy irradiation results in an athermal movement of the interstitial even at 4.2 K. This is believed to be caused by an ionisation enhanced defect motion [2]. Similarly, rapid diffusion of interstitials occurs after 1.3 MeV proton implantation of n-Si. Hence, if the assignment is correct there must be some reason why the diffusion does not occur in the high energy proton irradiation experiments.

AA12 is not the only spectrum that has been assigned to a self-interstitial defect. The P6 EPR centre is formed in neutron, ion or MeV proton irradiated intrinsic Si [3,4]. Its g -tensor reveals a C_2 axis along [1 0 0] at 200 K, but at 300 K, the symmetry becomes D_2 or D_{2d} and anneals at 440 K. The activation energy for this change is only 0.2 eV and represents a thermally activated reorientation between equivalent sites. Uniaxial stress studies showed that the defect could reorientate at 100°C with an activation energy of 0.6 eV. This activation energy is similar to the anneal of the 0.4 eV DLTS level found in irradiated p-Si. The energy-stress tensor of P6 is consistent with a defect of D_{2d} symmetry with principal values and directions $B_1 = B_2 = 15.4$ eV along [1 0 0] and [0 1 0], and $B_3 = -30.8$ eV along [0 0 1]. Here, the C_2 axis in the low temperature form points along [0 1 0] through the unique Si atom.

Lee et al. [3] suggested that P6 is due to I_2^+ with three atoms sharing a lattice site resulting in a C_2 axis along $[0\ 1\ 0]$. Recent ab initio calculations [5] indicate that this structure is metastable and I_2 possesses C_{1h} symmetry at low temperatures, and C_{2v} when some distortion is allowed. In spite of this difference in symmetry, the defect was identified with P6. This cannot be correct and, therefore, the true nature of P6 is at present unresolved.

The results derived in this paper have been found using a first principles density functional method employing Gaussian orbitals (AIMPRO) [6]. The calculations for the energies have been carried out in supercells, but the electrical levels have been calculated from the ionisation energies of the defects, when embedded in large H-terminated clusters in a way described previously [7].

2. Single interstitial I_1

A number of possible locations for the interstitial were examined in 65 atom supercells. These were the T site with T_d symmetry, the H site with D_{3d} symmetry and the $\langle 110 \rangle$ -split interstitial with C_{2v} symmetry. In the neutral charge state the energies of the T interstitial and the $\langle 110 \rangle$ -split interstitial are equal to within the precision of the method (Table 1). The H interstitial is found to be about 0.16 eV higher in energy. The potential well in which the T interstitial is located is quite narrow and a small displacement of the interstitial can push it towards the H site lowering the symmetry to C_{3v} . This is probably due to a Jahn–Teller effect to be discussed below. In the negative charge state the $[1\ 1\ 0]$ oriented interstitial has the lowest formation energy, while the T interstitial in the $1+$ and $2+$ charge states has the lowest energy. In the $2+$ state, the T site is stable against small perturbations, i.e. when moved slightly from its equilibrium position, the atom returns during the relaxation. In general, the results for I_1 are in agreement with previous theory [8,9]. The formation energy for the interstitial at the T site in the neutral

charge state is found to be 3.36 eV, in good agreement with a previous calculation of 3.43 eV [9]. Increasing the supercell to 129 atoms or the MP scheme to 4^3 enhances the formation energy by only 0.05 and 0.01 eV. Therefore the calculations are converged with respect to the size of the supercell and the k -point sampling.

Electrical levels of the single interstitial were found by taking the relaxed structures from the supercell and embedding them in 297 atom clusters. Ionisation energies were then calculated and compared with standard defects such as hydrogen at a BC site, interstitial carbon, substitutional sulphur and the sulphur pair. The ionisation energy was then found using the difference in energy between the ionised and neutral defects [7]. The T interstitial possesses a t_2 level in the upper part of the gap which is occupied by two electrons when neutral. In this case a Jahn–Teller distortion splitting the t_2 manifold would be expected. This is probably the origin of the C_{3v} distortion. However, it seems that the distortion is small.

Table 2 gives the calculated ionisation energies and donor levels evaluated using the sulphur pair as a reference. We choose this as it has a $(+/++)$ level very close to that of AA12. The error in the method is about 0.2 eV. The single donor level of I_1 at the T site is above the conduction band and thus the interstitial is always ionised at the T site. On the other hand, the $[1\ 1\ 0]$ split interstitial has a donor level close to E_v and thus is only neutral in this site. Hole trapping of the neutral defect must then lead to a switch to the T site and subsequent

electron trapping would reverse this site change. In this way, rapid athermal diffusion could occur at low temperatures in the presence of irradiation. We find the second donor level of I_1 at the T site to lie at $E_c - 0.08$ eV and about 0.31 eV above the level attributed to AA12. This is at the very upper error limit expected in the method. This level should also exhibit a Poole-Frenkel effect. In the positive charge state, a Mulliken analysis shows that 7% of the spin density is localised on the interstitial in the three p-orbitals. The isotropic hyperfine interaction with the nucleus of the unique Si atom is then almost zero, consistent with low 1.5% value seen experimentally for AA12.

The diffusion barrier of the interstitial at the T site was then investigated. The H site is a saddle point on the diffusion path of I_1^{++} . The barrier in this charge state is found to be about 1 eV. If we use the Arrhenius diffusion equation $D = D_0 \exp(-Q/kT)$ with $D_0 = va^2$, where a is the distance between T sites ($a/\sqrt{2}$) and $v = 10^{13} \text{ s}^{-1}$, then the temperature at which the defect anneals is around 350 K, consistent with the anneal of the AA12 centre. In the metastable neutral charge state the diffusion barrier for T-H-T path is found to be below 0.2 eV, which is also consistent with the measured annealing of AA12 around 80 K under minority carrier injection.

3. Di-interstitial

Several structures with C_2 symmetry were first considered, being the most stable similar to the P6 model proposed by Lee et al. [3]. In this structure, shown in Fig. 1(L), two Si atoms are placed symmetrically around a substitutional atom roughly aligned along a cube axis. The original substitutional atom is displaced along $[010]$. We call this the L form. This is, however, not the lowest energy structure of I_2 . A lower energy structure for the neutral charge state has C_{1h} symmetry and is identical to that proposed by Kim et al. [5] and shown in Fig. 1(K). This structure can be found by placing an Si dimer, oriented along $[011]$, near to a substitutional atom. This atom is displaced away from the dimer so that the symmetry becomes C_{1h} with a (011) mirror plane. There is, however, another structure also having C_{1h} symmetry with comparable energy. This form, Fig. 1(C), is described in Ref. [10]. The C form is structurally very similar to the K form, but the $[011]$ dimer is added to a site near a bond centre, maintaining a (011) mirror plane. The formation energies of the neutral C, K, L forms of I_2 are 5.12, 5.19 and 6.17 eV. Table 3 shows the relative energies in each charge state. Clearly, the L form has an energy about 1 eV higher than the C_{1h} forms in all charge states. The K and C defects have competitive energies in all charge states.

Table 2 shows that the $(0/+)$ level of the stable C form of I_2 lies at $E_v + 0.3$ eV.

The diffusion energy of neutral I_2 was found by imposing constraints preventing the diffusing structure to relax to the equilibrium one [11]. The diffusion barrier along the path is quite complicated and is illustrated in Fig. 2. Step (i) shows the starting structure in the C form. The first step (ii) represents the transition to the saddle point between two symmetric versions of the C form. This costs 0.5 eV. Step (iv) involves a relaxation to the K form which is almost degenerate with the C form. Step (v) involves the movement of the single Si atom to a symmetric version of the K form (vi). The next step

Fig. 1. Models of I_2 .

Table 3

Relative energies, eV, for the three forms of I_2 in various charge states

Charge	L	C	K
-1	1.07	0.00	0.04
0	1.05	0.00	0.07
+1	1.12	0.00	0.007

Fig. 2. Energetics of the diffusion path for I_2 .

takes us to the C form (vii). The steps (vii)–(x) complete the movement of the dimer through a lattice vector $a/\sqrt{2}$. Thus, the net migration barrier is about 0.5 eV. It is possible that another diffusion path exists with lower energy. Preliminary calculations also show that the migration barriers for the lowest energy I_3 is approximately 0.75 eV in the neutral charged state. These dramatic results show that both I_2 and I_3 are likely to diffuse *faster* than I_1^{++} .

We complete our investigation into I_2 by calculating the stress-tensor B for the L defect in a way described previously [11]. Relaxing the cell volume leads to an expansion of 0.8% and 0.3% for the neutral and positive defects, respectively. The B -tensor for the positive defect has principal values and directions $B_3 = -7.5$ eV along $[0,0,-0.3,1,0]$, $B_2 = 6.1$ eV along $[0,0,1,0,0.3]$, and $B_1 = 1.5$ eV along $[1,0,0]$. Now, the observed values for P6 corresponding to the high temperature D_{2d} form are $B_1 = -30.4$ eV, along $[1,0,0]$, and $B_2 = B_3 = 15.4$ along $[0,1,0]$ and $[0,0,1]$, respectively. Clearly, the calculated values are very different from the experimental ones. This suggests that P6 is a distinct defect from I_2 .

4. Conclusions

We have shown that the single interstitial is stable at the T site in the positive and double positive charge state, and that it has symmetry and spin density consistent with the AA12 EPR centre. The calculated diffusion barrier of I_1^{++} is in agreement with the thermal annealing of AA12 in the dark at 350 K, and the lower diffusion barrier found for I_1^+ accounts for the loss of AA12 under electron injection. However, the $(+/++)$ calculated level is much more shallow than $E_c - 0.39$ eV reported for AA12. Therefore, we conclude that the AA12 defect is probably the long-sought self-interstitial, although there is uncertainty about the position of the second donor level. The calculations show that the defect does not possess a first $(0/+)$ level within the gap and the neutral defect would spontaneously ionise.

Turning to the di-interstitial we conclude that the lowest energy configuration found by Kim et al. is not the P6 EPR centre. Further, the Lee et al. model for I_2 is only metastable and has a B -tensor at variance with P6. The calculated diffusion barrier for I_2 is 0.5 eV, half that of I_1^{++} . The rapid mobility of I_2 at room temperature explains the absence of a dominant EPR centre that can be assigned to the defect. Other forms [12] are compact and highly mobile like I_2 . Thus, we expect I_4 defects to be formed at the same time as I_3 . I_4 has been linked with the B3 EPR centre which is known to be stable up to 500°C. This scenario of several coexisting self-interstitial aggregates is distinct from that assumed in sequential kinetic models of the growth of I_n clusters [13].

Abstract

The radiation-induced defects, which give rise to the absorption bands at 956, 944 and 936 cm⁻¹ in silicon and are suggested to be the self-interstitial–interstitial-oxygen-related complexes IO_i and I₂O_i, have been studied by FTIR. N-type C-rich Si crystals co-doped with ¹⁶O and ¹⁸O isotopes were irradiated at $T = 80$ K with 5 MeV electrons and then annealed isochronally up to 360 K. The oxygen isotopic shifts of the bands assigned to IO and I₂O are determined and a direct evidence of the oxygen incorporation in the defects is presented. Appearance of a number of new bands has been observed upon the interstitial carbon C_i annealing and they are attributed to precursors of the C_iO_i complex. © 2001 Elsevier Science B.V. Keywords: Silicon; Irradiation; Self-interstitials; Oxygen isotopes

1. Introduction

The silicon self-interstitial (I) is a fundamental intrinsic defect, which is always produced during Si crystal growth as well as in the course of high temperature processing and/or irradiation treatments. However, the isolated interstitial has not been properly identified, yet, which is probably due to its high migration ability [1]. It can interact efficiently with many other defects and impurities, resulting in the appearance of new centers. The best known process is the Watkins replacement mechanism when the group III impurities and substitutional carbon are ejected into interstitial sites [1,2]. Interaction of the Si self-interstitial with the interstitial oxygen (O_i) has also been proposed to play an important role in processes of radiation defect formation as well as in oxygen agglomeration at elevated temperatures [3,4]. In particular, enhanced oxygen diffusion was suggested to occur via a highly mobile IO_i complex [5–7]. Besides, such a complex was argued to be the core of the oxygen-related thermal double

donors [8]. However, experimental data available on the IO_i complex are controversial.

In 1966, Whan [9,10] revealed three vibrational IR absorption bands located at about 936, 944 and 956 cm⁻¹ at 80 K in irradiated Czochralski-grown silicon (Cz-Si). These bands were later assigned to arise from the IO_i complex. The bands appeared after irradiation by fast electrons at temperatures 80–150 K of oxygen-rich Si crystals, but not in oxygen-lean ones [9,11,12]. The presence of Ge or Sn (traps for vacancies) did not affect the formation of the 936, 944 and 956 cm⁻¹ bands while doping by carbon (a trap for I) reduced their formation substantially [12]. The bands at 944 and 956 cm⁻¹ are most likely associated with different configurations of the same center since their relative intensities could be changed reversibly at low temperatures upon the sample illumination and/or storage in darkness [9]. Both bands annealed out at about 200–250 K with a partial transformation into the 922 and 932 cm⁻¹ bands, related to interstitial carbon, and into the 936 cm⁻¹ band [11,12]. The 936 cm⁻¹ band anneals out already at about 350 K with a simultaneous increase in the intensity of the 9 μm band, i.e., in the concentration of interstitial oxygen atoms.

*Corresponding author.

E-mail address: lukh@iop.kiev.ua (L.I. Khirunenko).

These facts allowed all the three bands (at 944, 956 and 936 cm^{-1}) to be assigned to arise from the IO_i complex [12,13]. However, there are some observations that are not consistent with such an assignment for the 936 cm^{-1} band. Firstly, no IO_i complex that is stable at RT has hitherto been observed by any other technique. Secondly, there is a consensus that the IO_i complex is indeed formed during LT irradiation of the Cz-Si crystals, but it has also been established that the complex is only stable up to about 200–250 K. Dissociation of the IO_i complexes in this temperature region has been manifested in many experiments [11,12,14–17] via correlated appearance of interstitial carbon and/or aluminum atoms. Furthermore, similar thermal stability behavior of IO_i complexes was confirmed by the EPR technique [16]. Evidently, the 936 cm^{-1} band should arise from another, more stable defect. The Si interstitial pair and interstitial oxygen complex, I_2O_i , have been suggested recently [18,19] to be responsible for this band. Such a complex may be formed via the reaction $\text{I} + \text{IO}_i \rightarrow \text{I}_2\text{O}_i$.

Apparently, the local vibrational modes (LVMs) at 936 and $944\text{ (}956\text{)}\text{ cm}^{-1}$ could be related to oxygen vibrations in the I_2O_i and IO_i complexes. To get a direct evidence of this, in the present paper, we have performed an IR absorption study of low-temperature radiation-induced defects in Si crystals co-doped with ^{16}O and ^{18}O isotopes.

2. Experimental

The relatively low resistivity ($0.2\text{--}0.3\ \Omega\text{ cm}$) n-type Si samples co-doped with oxygen isotopes ^{16}O and ^{18}O were used in this study. The ^{16}O , ^{18}O and carbon concentrations were determined from the intensity of the bands at 1107 , 1058 and 605 cm^{-1} at room temperature [2,20] and were about 1×10^{18} , 8×10^{17} and $4 \times 10^{17}\text{ cm}^{-3}$, respectively. Irradiation with electrons (5 MeV) was performed to doses $(3\text{--}5) \times 10^{17}\text{ cm}^{-2}$ using a microtron. The temperature of the samples during irradiation was about 80 K, after irradiation the samples were moved to a cryostat without heating. The isochronal annealing was carried out in temperature steps of 3–10 K in the range 80–363 K, for 15 min at each temperature. Absorption spectra were measured using a Bruker 113v Fourier Transform IR Spectrometer at 10 K with spectral resolution of 0.5 cm^{-1} .

3. Results and discussion

3.1. Si self-interstitial-oxygen related defects

Figs. 1a and b show typical infrared absorption spectra measured at 10 K in the region of 780–

Fig. 1. Absorption spectra measured at 10 K for Si: ^{16}O , Si: ^{18}O and Si: C after irradiation at 80 K for a dose $5 \times 10^{17}\text{ cm}^{-2}$ (1) and subsequent annealing at 300 (2) and 363 K (3).

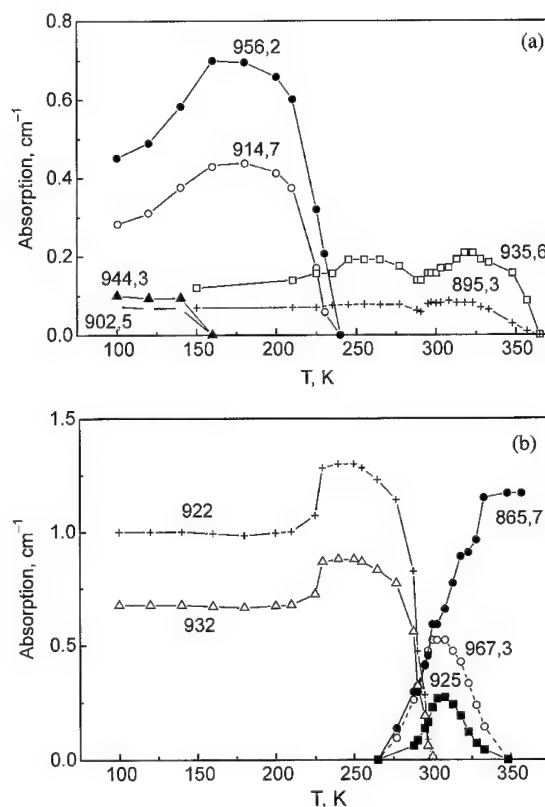

Fig. 2. The behavior of the absorption bands at annealing of irradiated Si: ^{16}O , ^{18}O , C.

980 cm^{-1} for investigated samples after irradiation at 80 K (1) and annealing at 300 (2) and 363 K (3). The annealing behaviors of some of the bands are shown in more detail in Figs. 2a and b, and their positions are

given in Table 1. In the as-irradiated sample, the most prominent bands at 836 and 800 cm^{-1} are due to oxygen (^{16}O and ^{18}O) vibrations in the neutral vacancy-oxygen (VO) center. The weaker bands at 885 and 847 cm^{-1} are related to the same center but in its negative charge state. The well-known bands at 922 and 932 cm^{-1} originate from C_i atoms. The bands at 944, 956 and 936 cm^{-1} appear to be the same as those observed previously [9–13,18,19] in Si: ^{16}O crystals, i.e., the former two arise from the IO_i complex, and the latter from the I_2O_i defect.

Of particular interest, here, are the bands at 903, 915 and 895 cm^{-1} . A linear correlation was found between the intensities of the former two bands and the bands at 944 and 956 cm^{-1} in samples irradiated with different doses, and the ratio of intensities was close to that of the ^{16}O and ^{18}O concentrations. Besides, all these bands have an identical annealing behavior, as illustrated in Fig. 2b. It should also be noted that the 903 and 915 cm^{-1} bands display reversible changes in intensity under illumination similar to those of the bands at 944 and 956 cm^{-1} . All these facts allow us to assign the 903 and 915 cm^{-1} bands as arising from an I^{18}O_i complex. In a similar way, the band at 895 cm^{-1} is found to be an ^{18}O isotope analog of the 936 cm^{-1} band, i.e., it is likely related to an I_2O_i defect. Both the bands (at 895 and 936 cm^{-1}) anneal out at about 350 K and their disappearance is accompanied by a decrease in intensity of the bands related to the A-center (see spectra (2) and (3) in Fig. 1b). Probably, the VO defect is the most efficient trap of I atoms released upon the I_2O_i dissociation.

It is worth mentioning that the observed oxygen isotopic shifts of the bands at 944, 956 and 936 cm^{-1} are typical for the asymmetrical stretching vibrations of divalent oxygen in Si. The data obtained may be useful when modeling the structure of IO and I_2O centers.

3.2. Interstitial carbon–oxygen related defects

One of the important findings of the present study is an observation of a number of new bands, appearing upon annealing of C_i (bands at 922 and 932 cm^{-1}) in the temperature range 270–300 K. The most intensive of them are located at about 925 and 967 cm^{-1} (see Fig. 2b). The newly observed defects are not very stable and start to anneal out at $T \geq 300$ K. Their disappearance results in a significant growth of the well-known band at 866 cm^{-1} related to the C_iO_i defect (e.g., see review [2] and references therein). It appears most likely that the new defects are precursors (some intermediate states) to a stable configuration of C_iO_i . Such a suggestion is in agreement with the results of previous DLTS studies [21], where a metastable configuration of this complex has been found. It should be noted that another well-known carbon-related defect, CsCi , is also formed via a metastable complex [2,22].

The bands at 925 and 967 cm^{-1} , according to their separation and relative intensities, are likely related to ^{18}O and ^{16}O vibrations in one of the C_iO_i metastable configurations. In such a configuration, the oxygen atom is probably two-coordinated (divalent) while in the most stable one, it is over-coordinated (trivalent) and gives rise to the band at 742 cm^{-1} [23]. The C_i -related bands are also expected for metastable C_iO_i states and there are some candidates. However, further studies are needed to identify them properly.

Divacancies in proton irradiated silicon: characterization and annealing mechanisms

R. Poirier*, S. Roorda, F. Schiettekatte, M. Lalancette, J. Zikovsky

Groupe de Recherche en Physique et Technologie des Couches Minces et Département de Physique, Université de Montréal, C.P. 6128 Succ. Centre-Ville, Montréal, Québec, Canada, H3C 3J7

Abstract

Annealing of divacancies produced by ion bombardment of crystalline silicon has been characterized using differential scanning calorimetry (DSC) and Fourier transform infrared absorption (FTIR). DSC at a rate of 40°C/min shows two clear peaks in the heat release, one at 140°C and the other at 240°C. The activation energies of these peaks were calculated assuming first order kinetics and found to be approximately 1.2 and 1.5 eV. The remaining fraction of divacancies with respect to annealing temperature was measured by FTIR and compared to the remaining fraction of defects calculated from the heat released in DSC. Annealing measurements are in agreement with previous work on electron and neutron irradiation of Si despite much higher defect concentrations. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon; Divacancy; Ion implantation; Calorimetry; Annealing

1. Introduction

Despite more than three decades of work on vacancies and divacancies in crystalline silicon, some important aspects of these point defects are not completely known and understood. In particular, the formation energy of divacancies has yet to be measured experimentally. Our aim is to measure that formation energy. Several studies were conducted on electron irradiated Si [1]; however, defect concentrations were always much lower than in ion irradiated Si. In this paper we describe the preparation and characterization of Si samples with divacancy concentrations high enough to be used for such a measurement.

Divacancies are produced by bombardment with 8 MeV protons which have enough energy to completely go through the samples and produce defects without leaving residual hydrogen which would react very effectively with vacancy-type defects to produce unwanted point defects in our material [2,3]. The total amount of divacancies in an irradiated sample can be

measured using infrared absorption [1,4], electron spin resonance (ESR) [5], positron annihilation study (PAS) [6] and deep level transient spectroscopy (DLTS). However, a quantitative evaluation of the divacancy count in a sample is very difficult to achieve. We plan to eventually do this by establishing a correlation between these different methods. The heat released during a thermal anneal measured using differential scanning calorimetry (DSC) clearly indicates two annealing mechanisms of different activation energies. This raises questions about the annealing behaviour of divacancies that must be answered before we can evaluate their formation energy by simply taking the ratio of the heat released to the total number of divacancies in the sample.

2. Sample preparation and analysis techniques

The samples were cut from three types of $\langle 111 \rangle$ float-zone crystalline silicon manufactured by Wacker: nominally undoped Si which is in fact a high resistivity ($> 7000 \Omega \text{cm}$) N-type crystal, N-type Si with a resistivity of about 60 cm and P-type Si with a resistivity of about

E-mail address: poirier@lps.umontreal.ca (R. Poirier).

100 Ω cm. The dopant concentrations in the N-type and P-type samples are lower than $1 \times 10^{14} \text{ cm}^{-3}$ while oxygen and carbon impurities concentrations are lower than 1×10^{16} and $2 \times 10^{16} \text{ cm}^{-3}$, respectively. These are two orders of magnitude lower than the divacancy concentration in irradiated sample as measured by Fourier transform infrared absorption (FTIR).

High energy proton bombardment of silicon is used to create vacancies in the crystalline structure by displacing atoms. Vacancies have a high diffusivity at room temperature and can coalesce into divacancies [7]. To limit emitted radiation during and after the experiment, early bombardments were made with 3.5 MeV protons and the samples were thinned by mechanical polishing to 100 μm using SiC grinding disks to allow the protons to go through them. Reproducibility was difficult to obtain by this method and the thinning process was abandoned. We now rather use 8 MeV protons which have sufficient energy to go through 300 μm of Si while losing approximately 3.5 MeV in the sample. Samples are irradiated to a fluence of $5 \times 10^{16} \text{ ion/cm}^2$ with a beam current below 750 nA rastered over an area of 9 cm^2 , thus keeping the areal power density below 0.3 W/cm^2 . Furthermore, the samples are kept at liquid nitrogen temperature (77 K) during bombardment to avoid dynamical annealing of vacancies. After bombardment the samples are allowed to warm to room temperature and cut in pieces of approximately $5 \times 5 \text{ mm}^2$.

The irradiation damage was characterized with a Bomem DA3 Fourier transform infrared spectrometer with a CaF_2 beamsplitter and liquid-nitrogen-cooled MCT detector. A broad absorption peak around 1.8 μm associated with the divacancy [1,4] was observed in all irradiated samples. The absorbance (αd) of the 1.8 μm band, defined as the logarithm of the ratio of the sample intensity and of a reference intensity of an unirradiated sample measured under identical conditions, can be related to the areal density of divacancies (N_{vv}) in our sample using the criterion developed by Stein and co-workers [4] by the equation $N_{\text{vv}} = (\alpha d) 7.7 \times 10^{16} \text{ divacancies/cm}^2$.

The heat released during annealing of the radiation damage was monitored with a Perkin-Elmer DSC7 differential scanning calorimeter flushed with dry argon gas [8,9]. Two or three pieces of bombarded Si were stacked together in the sample pan of the DSC while the same number of unirradiated Si were loaded in the reference pan. Three identical scans from 20°C to 400°C at a rate of 40°C/min were made for each measurement, preceded and followed by an isotherm of several minutes to allow the calorimeter to stabilize. The difference between the first and second scan represents the heat released by defect annealing in the sample, while the third scan allowed us to ensure that the baseline remained constant between consecutive scans.

3. Results and discussion

Fig. 1 presents a DSC scan of two irradiated samples at a rate of 40°C/min. Two peaks are clearly observable, one at 140°C and the other at 240°C, thus identifying two distinct annealing mechanisms for divacancies in c-Si. Assuming first order kinetics and a constant prefactor of 15 THz, a typical phonon frequency in silicon, the activation energies of these processes are found to be approximately 1.2 and 1.5 eV. The positions of the peaks varies with scanning rate but the calculated activation energies remain constant. The values of these activation energies are bound to change depending on the validity of our assumptions which remain to be checked through isothermal annealing. Nevertheless, the activation energy of 1.2 eV agrees closely with values obtained from neutron and electron irradiation of silicon and is associated with the onset of divacancy migration [1,10]. The second mechanism remains to be identified, however it could be due to divacancy dissociation. The heat released may be integrated to yield the evolution of the divacancy concentration as shown in Fig. 2. Of course, by doing so we assume that the heat released is only due to divacancies, and that there is no contributions from simultaneously annealing interstitials, for example.

The divacancy concentration in ion irradiated samples, as measured by FTIR, is approximately 10^{18} cm^{-3} , while it was about 10^{15} cm^{-3} for electron irradiated Si with similar fluences [5]. Fig. 2 shows the fraction of remaining divacancies as measured by FTIR and calculated from the DSC curve from Fig. 1. The samples in the first set (open symbols) were thinned to 100 μm

Fig. 1. DSC scan of two irradiated samples at a rate of 40°C/min. Two peaks are clearly observable, one at 140°C and the other at 240°C. Activation energies of 1.2 and 1.5 eV for the two processes respectively are obtained by fitting the peaks using first order kinetics and a constant prefactor of 15 THz.

Fig. 2. Remaining fraction of divacancies as measured by FTIR and calculated from the DSC curve from Fig. 1. (A) Open symbols: 100 μm samples bombarded with 3.5 MeV protons annealed 15 min at the indicated temperature. (B) Solid circles: 300 μm samples bombarded with 8 MeV protons scanned from 20°C to the temperature T and back at a rate of 80°C/min. The dotted line is only a guide for the eye. (C) Solid line: remaining fraction of divacancies calculated by integrating the DSC curve in Fig. 1, assuming that the heat released is entirely due to divacancy annihilation.

and bombarded with 3.5 MeV protons before being annealed 15 min at the indicated temperature. No discernable difference between the three types of silicon can be observed. This either indicate that dopants concentration ($<10^{14} \text{ cm}^{-3}$) is too low to have an influence on the annealing mechanism or that they do not play a significant role in divacancy annihilation behaviour. This curve is comparable to the annihilation curve of neutron damage in silicon [10] even though defect concentrations were several orders of magnitudes higher in this study.

For the second set of data (filled circles), the samples were scanned in temperature from 20°C to the temperature T and immediately cooled at a rate of 80°C/min. The sample therefore received an equivalent thermal treatment and the results could then be directly compared to the third set of data (solid line) calculated by integrating the DSC curve in Fig. 1. If the heat released during annealing is entirely due to divacancies and if the 80°C/min scan and DSC are equivalent, the second and third data set would coincide. Since they do not, either the kinetics are different or another process is emitting heat in the irradiated samples. This heat release

could be associated with the background shown by the dotted line in Fig. 1 and must be related to annihilation of defects not visible by FTIR.

4. Conclusions

DSC measurements clearly show two distinct peaks in the heat released during annealing of proton irradiated silicon. The activation energies of these peaks were calculated assuming first order kinetics and found to be approximately 1.2 and 1.5 eV. The remaining fraction of divacancies with respect to annealing temperature was measured by FTIR and compared to the remaining fraction of defects calculated from the heat released in DSC. This comparison appears to indicate that the heat released during annealing is in part due to defects other than the divacancy. Our annealing measurements are in agreement with previous work on electron and neutron irradiation of Si in spite of much higher defect concentrations.

Do we know the energy levels of radiation defects in silicon?

L.F. Makarenko

*Department of Applied Mathematics and Computer Science, Belarus State University, F. Skaryna Avenue 4,
220050 Minsk, Belarus*

Abstract

The validity of a single-level model to interpret temperature dependences of charge carrier concentration in n-Si crystals irradiated by ^{60}Co gamma-rays is investigated. It is shown that the consideration of a vacancy–oxygen complex (A-center) in silicon as an isolated monovalent defect with energy level close to $E_c - 0.17\text{ eV}$ does not allow to describe adequately Hall effect data for crystals in which the A-center is dominant. From carbon related complexes the single-level model is adequate only for interstitial carbon C_i . The explanation of experimental data for a $C_i - C_s$ complex requires more complex models. The acceptable description of experimental dependences of $n(T)$ can be achieved only within the framework of various two-level models. However, the acceptance of any of them entails a conclusion that the investigated radiation defects are coupled in pairs even at very low irradiation fluences. © 2001 Elsevier Science B.V. Keywords: Silicon; Radiation defects; Energy levels

1. Introduction

For high-energy physics, particle detectors are required that keep their efficiency even when the concentration of radiation defects exceeds 100 times the concentration of doping impurity in weakly doped regions of the detector. It stimulated intensive investigations of radiation damage of detector-grade silicon (see review [1] and references therein). It would seem that the problem to develop prognostic models quantitatively predicting changes of performance characteristics of detectors under irradiation is quite easy. This opinion can be based on the knowledge accumulated over more than 40 years of development of radiation physics of silicon. Many efforts were spent for studies of detectors by deep level transient spectroscopy. Nevertheless, being based on the obtained data, it was not possible to establish a prognostic model which included as initial parameters, at first, defect concentration, entropy (ΔS_i) and enthalpy (ΔH_i) of ionization, capture cross-sections of charge carriers and, secondly, used known methods of

processes simulation in semiconductor devices. The models developed till now have a semi-empirical character [1]. This, in our opinion, can be related to incompleteness of radiation defect models. So, for example, for an oxygen–vacancy complex (A-center), two models have been suggested. The first model, which is generally accepted from the very beginning of radiation physics of silicon, describes the A-center as a defect with an acceptor level near to $E_c - 0.17\text{ eV}$ [2]. In Ref. [3] on the basis of magnetic spectroscopy data it was substantiated that the A-center is an amphoteric defect with an acceptor level near to $E_c - 0.17\text{ eV}$ and donor level near to $E_c - 0.76\text{ eV}$. Besides this it is necessary to take into account that the changes of characteristics of irradiated silicon detectors are due to the combined effect of several defects with close levels. For n-type silicon such defects are the oxygen–vacancy complex (V–O) and an interstitial carbon–substitutional carbon complex ($C_i - C_s$) which have their acceptor levels close to $E_c - 0.17\text{ eV}$ [4]. In this case it is difficult to establish what defect determines the kinetics of degradation processes in detectors and to optimize their radiation tolerance. Therefore, at present there is a problem of developing methods to test models of

(L.F. Makarenko).

radiation defects in silicon and extract their parameters necessary for the following simulation of detector performance under irradiation.

2. Experimental results and discussion

Temperature dependences of the charge carrier concentration for silicon crystals irradiated with Co-60 gamma-rays are shown in Fig. 1. Czochralski-grown (oxygen-rich) and float-zone (oxygen-free) crystals were used (parameters of samples and details of experiment are described in Refs. [5,6]). For a preliminary estimation of occupancy levels for radiation defects under study it is possible to use differential curves (Fig. 2). One can see in the Czochralski-grown crystals a center with a level close to $F_{1\max} = E_c - 0.18\text{ eV}$ labeled here as $E \times (0.18)$. In the float-zone crystals a center with a level close to $F_{2\max} = E_c - 0.12\text{ eV}$ ($E(0.12)$) appeared immediately after irradiation at 200 K. After annealing at 375 K it disappeared and the appearance of a new defect $E(0.16)$ is observed.

The behavior of both types of crystals is familiar and well-known from the literature. In oxygen-rich silicon the oxygen-vacancy complex (the A-center) is formed. The concentration of other defects is negligibly small.

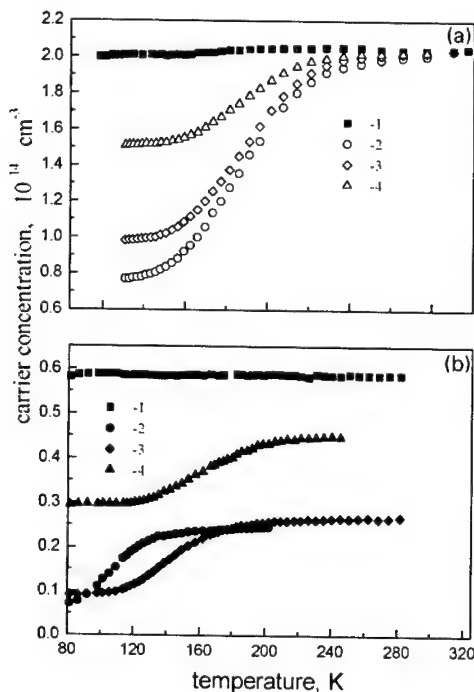

Fig. 1. Temperature dependences of the carrier concentration in n-Si with high (a) and low oxygen content (b): 1—as-grown crystals, 2—after gamma-irradiation, and 3,4—after subsequent annealing at different temperatures.

Fig. 2. Dependences of Δ_H on the distance (F) between the conduction band bottom (E_c) and the Fermi level (E_F) for interstitial C_i (1) and C_i-C_s (2) calculated from the 2nd and 3rd curves of Fig. 1(b), for O-V (3) complex calculated from curve 2 of Fig. 1(a).

The A-center is annealed at $T > 300^\circ\text{C}$. Formation of new electrically active defects is not observed with Hall-effect measurements. In oxygen-free crystals interstitial carbon (C_i) with occupancy level at $E_c - 0.12\text{ eV}$ ($E(0.12)$) and a phosphorus-vacancy complex (E-center) with an occupancy level at $E_c - 0.4\text{ eV}$ are observed after low temperature irradiation. At temperatures higher than 300 K, C_i becomes mobile. Migrating in the lattice it is trapped by a substitutional carbon atom (C_s). As the result a C_i-C_s complex with an energy level of $E_c - 0.16\text{ eV}$ is formed. As the annealing temperature is raised to 400 K, the E-center starts to anneal and the charge carrier concentration is increased. Simultaneously the concentration of $E(0.16)$ decreases, and the new defect with an energy level of $E_c - 0.20\text{ eV}$ ($E(0.20)$) appeared. The different amplitudes of the $\Delta_H(F)$ graphs in Fig. 2 are explained within the framework of a single-level model as due to different values of ionization entropy of the defects (ΔS_i). The less ΔS_i , the lower the maximum value of $\Delta_H(F)$.

It seems that the best way to estimate the adequacy of models used for interpretation of Hall effect data is the method of least squares with the subsequent analysis of residuals. Different suggestions on numbers of simultaneously ionized defects and of their charge states were used in this work. Concentration of charge carriers can be calculated from the neutrality equation. When in a semiconductor two simple centers (N_γ and N_β) and an amphoteric (N_i) center are available this equation reads

$$N_{\text{net}} = n + N_\gamma f_1(T, F, X_\gamma) + N_\beta f_1(T, F, X_\beta) + N_i f_2(T, F, X_i), \quad (1)$$

where f_1 and f_2 are occupation functions of single- and two-level centers, respectively, \mathbf{X} is a vector, whose components are ionization entropies and enthalpies of the centers (S_i, H_i , etc.).

The simplest of the used models is a single-level one when the change of carrier concentration with temperature is due to ionization of one simple monovalent defect ($N_\alpha \neq 0, N_\beta = 0, N_\gamma = 0$). The second model, utilized by us, is two-level I, in which ionization of two simple defects with close levels is considered ($N_\alpha \neq 0, N_\beta \neq 0, N_\gamma = 0$). The third model is two-level II when ionization of one divalent center takes place ($N_\alpha = 0, N_\beta = 0, N_\gamma \neq 0$).

The application of least squares method to Hall effect data consists in finding the minimum value of objective function

$$Q(\mathbf{X}) = \sum_i \left(\frac{n_{\text{fit}}(T_i, \mathbf{X}_N) - n_{\text{exp}}(T_i)}{n_{\text{fit}}(T_i, \mathbf{X}_N)} \right)^2 = \sum_i \delta_i^2, \quad (2)$$

where \mathbf{X}_N is the \mathbf{X} vector extended with concentrations of centers ($N_\alpha, N_\beta, N_\gamma$). The $n_{\text{exp}}(T_i)$ quantity is experimentally measured value of carrier concentration at the temperature of T_i , and $n_{\text{fit}}(T_i)$ is a value calculated from the appropriate neutrality equation setting temperature as T_i , and parameters of defects as \mathbf{X} . Secondly, after finding the minimum of the objective function the analysis of an error distribution of measurements is carried out.

Residuals included in Eq. (2) can be represented as $\delta_i = \delta_{i\text{random}} + \delta_{i\text{bias}}$. A random component $\delta_{i\text{random}}$ is connected to fluctuations of the current and Hall voltage during measurements. The biases determine the value of $\delta_{i\text{bias}}$ (for more extended discussion of errors see Ref. [5]). As measurements of n_{exp} at every temperature T_i are independent from each other, random component of residual is dominant and the graph $\delta_i(T)$ will look like a random variable with zero mean and approximately equal numbers of positive and negative values. If the model used to interpret experimental data is not true then a trend (nonrandom component) in $\delta_i(T)$ appears.

For the A-center first of all we estimate applicability of the single-level model with parameters determined by Wertheim in Ref. [7]: $\Delta H_i = 0.160$ eV and $\Delta S_i = -1.3$ k eV/K. As obvious from Fig. 3 (curve 2) this model results in too large values δ_i and a nonrandom course of the $\delta_i(T)$ dependence. The application of the single-level model with minimization of all parameters gives estimations of $\Delta H_i = 0.145$ eV and $\Delta S_i = -2.3$ k eV/K (the scattering of their experimental values is shown in Fig. 4) which agree with the results obtained in Ref. [8] for low irradiation doses. However, the estimated value of ionization enthalpy does not agree with the value $\Delta H_i = 0.17$ eV determined from measurements of strongly compensated crystals [8].

Fig. 3. Temperature dependences of relative residuals $\delta(T)$ for fitting by single-level (a) and two-level (b) models. Curve 1 (a) represents residuals for the C_i-C_s . Other data are for the A-center. For additional explanations see the text.

Fig. 4. Entropies and enthalpies of the A-center ionization estimated by the single- (1) and two-level II (2,3) models.

Distribution of residuals is not random (Fig. 3(a), curve 3) and their values are more than expected ones [5]. It allows us to draw a conclusion on inapplicability of the single-level model to describe occupancy function of the A-center.

Both two-level models result in much smaller values of residuals (Fig. 3(b), curves 2 and 3). The following parameters of defects are obtained. For two-level model I they are $\Delta S_i = (-0.3 \pm 0.7)$ k eV/K, $\Delta H_i = 0.159 \pm 0.009$ eV, $\Delta S_i = (+0.8 \pm 0.4)$ k eV/K, $\Delta H_i = (0.201 \pm 0.011)$ eV. For two-level model II: $\Delta S_{i42} = (-0.7 \pm 0.5)$ k eV/K, $\Delta H_i = (0.156 \pm 0.006)$ eV, $\Delta S_{i41} = (+0.2 \pm 0.6)$ k eV/K, $\Delta H_i = (0.202 \pm 0.011)$ eV. According to the values of residuals, both models are acceptable.

While analyzing data for interstitial carbon $E(0.12)$ it is necessary to take into account that in float-zone crystals along with carbon related centers the A-center can be also formed. Though in such crystals its concentration is small, its presence reveals in a high-temperature tail of $\Delta_i(F)$ dependence (Fig. 2, curve 1). Therefore, two-level model with fixed parameters of one defect (A-center) is to be used for data analysis. In following, this model is called a quasi-single-level model.

For C_i the values $\Delta H_i = 0.114$ eV and $\Delta S_i = -0.7$ kJ/K are obtained. The value of ionization entropy is equivalent to a degeneracy factor of $g = \frac{1}{2}$ as expected from the data of electron spin resonance experiments. The value of ionization enthalpy perfectly coincides with the activation energy of electron emission from $E(0.12)$ measured in Ref. [9]. So the occupancy function of C_i is well described by single-level model.

For the C_i-C_s complex the quasi-single-level model also results in small values of residuals (Fig. 3(a), curve 1). Estimated values for the defect parameters are $\Delta H_i = 0.125$ eV and $\Delta S_i = -3.2$ kJ/K. They do not agree however with the data obtained in other papers [4]. In our opinion such a small value of ionization entropy cannot be explained theoretically. More extended analysis of the Hall data for float-zone silicon will be published later [6].

Thus, it is possible to make a conclusion that from all the considered centers only interstitial carbon behaves as a simple monovalent defect. More studies are required to establish the actual models for the V–O and C_i-C_s complexes.

Till now all experimental data concerning the A-center in silicon were interpreted within the framework of a single-level model. A more or less consistent picture was developed to describe changes of electrical characteristics of the irradiated Czochralski-grown silicon. However, some experimental data are not satisfactorily explained within the framework of the single-level model. First of all those are the data on changes of ESR signal intensity of the A-center with irradiation fluence [5]. The application of the two-level models provides new capabilities to solve such problems.

It is necessary to select the most adequate model from the suggested ones. Both models suit to interpret the obtained Hall-effect data. But, as shown in Ref. [5] within the framework of the model of two independent defects it is difficult to achieve the agreement with data obtained by other methods. That is, the model of two coupled levels is preferable. However within the framework of this model two different assumptions on properties of the A-center are possible. The first one is the assumption of the amphoteric character of the A-center which was made in Ref. [5]. The second assumption is less obvious. As is known from studies of amorphous silicon [10], a pair of simple defects

behaves similarly as a divalent center and is characterized by just the same occupancy function. So one can interpret our data with an assumption that all the A-centers are coupled in pairs. Let us note that this assumption better agrees to the generally accepted mechanism of V–O complex annealing [11]. However, it requires a suggestion of a possible coupling mechanism.

However the acceptance of the second assumption needs finding a mechanism of pair correlation of these radiation defects. As shown above, one possible interpretation of the obtained data is the assumption that the A-centers are coupled in distant pairs. However it appears that the model of an amphoteric defect also entails the requirement about a pair correlation of radiation defects [5].

In general on the basis of all available data it is impossible to decide, which of the offered models is most adequate. To solve this problem more extensive studies with application of different experimental techniques are demanded.

3. Conclusion

In this paper radiation defects in silicon crystals irradiated with gamma-rays Co-60 are investigated using Hall effect measurements. The oxygen–vacancy complex prevails in the crystals with high oxygen content and carbon related centers (interstitial carbon C_i and pair C_i-C_s) are dominant in oxygen-free crystals.

With use of a least squares method, the validity of the single-level model to describe the occupation function of these defects is tested. It is established that this model can satisfactorily describe only the data for C_i . For the two other centers it is necessary to apply different two-level models. To come to an agreement of any of the two-level models with other data the assumption about a pair correlation of radiation defects in silicon is required.

However, the available data on the occupancy levels of the O–V and C_i-C_s complexes cannot be unambiguously interpreted.

Abstract

We performed a theoretical investigation on the interaction of arsenic impurities with a 30° glide partial dislocation in silicon. Our calculations were performed by ab initio total energy methods, based on the density functional theory and the local density approximation. We find that an arsenic atom, in a crystalline position, gives away one electron to the dislocation, becoming positively charged while the dislocation core is negatively charged. The interaction between arsenic and the core is essentially electrostatic, which leads to arsenic segregation. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Extended defects; Segregation; Dislocation

Dislocations are extended defects which are present in most crystalline solids. In semiconductors, they play an important role in the electronic properties of the material [1]. When dislocations are present in the active regions of the electronic devices, they give rise to leakage currents, as a result of dopant diffusion along the dislocation cores. On the other hand, dislocations are sometimes intentionally introduced far from the device active region to serve as sinks to undesirable impurities. In such context, the interaction of dislocations with point defects has received great attention recently [2,3].

In silicon, as well as in other zinc-blende semiconductors, dislocations generally belong to the {111} glide sets [4], lying along the $\langle 110 \rangle$ directions. It is energetically favorable for (screw and 60°) dislocations to dissociate into (30° and 90°) partial dislocations, with a stacking fault between the partials [5]. Dislocations move conservatively by thermally assisted formation and propagation of kinks [6], with the dislocation

velocity given by [4]:

$$v_d = v_0 \exp\left(-\frac{Q}{k_B T}\right), \quad (1)$$

where v_0 is a constant, Q is the activation energy, and k_B is the Boltzmann constant. Dopants can alter this dislocation activation energy. While $Q = 2.2$ eV in undoped silicon, it may decrease by as much as 0.5 eV [7,8] in n-type doped silicon. On the other hand, in p-type silicon, high concentrations of acceptor impurities increase the activation energy.

The interaction between dislocations and dopants could manifest itself as a non-local or as a local effect. The non-local effect results from the displacement of the Fermi level due to donor and acceptor doping. According to that model, the increase (decrease) in the dislocation mobility is a result of negatively (positively) charged dislocation cores, which decrease (increase) kink formation and migration energies [9]. The local effect would be the result of segregation of impurities in the dislocation core. For the dislocations to move, they should first break away from the impurity clouds which form in and around the dislocation cores. Therefore, dopant segregation towards the dislocation core controls

the dislocation pinning. Measurements have shown that the binding energies of impurities in the dislocation core are as large as 0.5 eV [10].

Here, we have used *ab initio* total energy calculations [11,12] to investigate the arsenic interaction with the core of a 30° partial dislocation in silicon. We used a reference orthorhombic periodic simulation cell with 192 atoms, in which a 30° partial dislocation dipole was introduced by displacing the atoms according to the solution for the displacement field of a dislocation [4]. Fig. 1 shows the simulation cell from three different side views. The cell geometry is such that the dislocations of the dipole are four lattice parameters apart along a $\langle 112 \rangle$ direction (about 13.5 \AA) in the glide plane, which is enough to prevent core–core interactions. Arsenic atoms were introduced in different sites of the simulation cell. Of particular interest was the arsenic segregation energy, i.e., the total energy difference between a configuration with the arsenic impurity in a crystalline site (the farthest position away from the dislocation core) and one with the arsenic sitting inside the dislocation core [3].

Our calculations were performed by a two-step relaxation procedure, first using an empirical potential and later *ab initio* methods. For the configurations shown in Fig. 1, we initially relaxed the atomic positions using an empirical potential [13,14] combined with a conjugate gradient minimization method. The output configurations were used as input to the *ab initio* calculations, where the atomic relaxation was based on the Hellmann–Feynman forces. The initial relaxation, based on the empirical potential, saved considerable computational effort in the *ab initio* calculations, by releasing most of the stress generated by the disloca-

tions. The *ab initio* calculations were performed within the density functional theory in the local density approximation. The Kohn–Sham equations for the electrons of the system were solved using the Car–Parrinello method [12,15] with norm-conserving pseudopotentials [16,17]. The electronic wave functions were expanded in a plane-wave basis-set with kinetic energy up to 12 Ry. The sampling in the Brillouin zone was performed using the Γ -point. Atomic relaxations were performed until the Hellmann–Feynman forces were smaller than 0.02 eV/\AA in all atoms.

We first considered a configuration with the arsenic impurity in a crystalline-like position, the farthest position (inside the simulation cell) away from the dislocation core. This configuration is indicated by atomic position number 1 in Fig. 1a. For such configuration, we observed that the arsenic impurity gives away one electron becoming positively charged. This charge is captured by the dislocation core, occupying a dislocation-related level [18]. In a reconstructed core, the first unoccupied level has a spatial dispersion inside the dislocation line, with an antibonding character with relation to the reconstructed dimers. As a result, the dislocation core will become negatively charged. These results are in agreement with recent measurements which found that dislocation cores are negatively charged in doped semiconductors [19]. The arsenic segregation energy was computed by comparing the total energies between configurations with the arsenic in the crystalline environment (position 1) and in the dislocation core (position 2). We find a segregation energy of 0.18 eV. This result is consistent with other theoretical investigations on arsenic interaction with a 90° partial dislocation, in which segregation energy of about 0.15 eV was found [20].

The interaction leading to arsenic segregation in the dislocation core is typically electrostatic. This interaction may be interpreted within a donor–acceptor model, or an ionic model [21]. In that case, the acceptor level is the dislocation-related antibonding level and the donor is the arsenic level. The donor level inside the materials gap is shifted deeper in the gap, and therefore deactivated, by the interaction with the acceptor. The donor level (E_d) inside the materials gap is given by [21]

$$E_d = E_\infty + E_{el} + E_c, \quad (2)$$

where E_∞ is the donor level for the isolated arsenic, E_{el} is the elastic interaction of the arsenic with the host lattice, and E_c is the Coulomb interaction between the negatively charged dislocation core and the positively charged donor. The shift in the donor level (with relation to the isolated arsenic) is

$$\Delta E_d = \Delta E_{el} + \Delta E_c. \quad (3)$$

We found that the arsenic presence distorts only slightly the lattice in either a crystalline site or inside the

Fig. 1. Atomic configuration of a dislocation in the $\{111\}$ glide plane. x , y , and z axes are respectively parallel to the $[1\bar{1}2]$, $[111]$, and $[\bar{1}10]$ directions of the zinc-blende lattice. The figure shows three configuration side views: (a) a plane normal to the dislocation line (xy -plane), (b) the glide plane where the dislocation belongs to (xz -plane), and (c) the plane along the dashed line (zy -plane).

dislocation core, as compared to the respective atomic configurations without arsenic. Arsenic in position 1 (Fig. 1) does not break the local symmetry, only relaxing the first neighbors to 2.40 Å, compared to 2.35 Å for the crystalline interatomic distance in Si. Arsenic in position 2 also keeps the symmetry of the dislocation core dimer. Distance in the dimer (2, 3) changes from 2.45 Å in pure silicon to 2.50 Å with the arsenic impurity in position 2. Elastic interaction between arsenic and the lattice is negligible. Therefore, we can assume that $\Delta E_{cl} \approx 0$, and the shift of the donor level essentially results from a Coulomb interaction [22]. In that sense, we speculate that the shift in the donor level is essentially determined by the arsenic segregation energy.

Table 1 presents the segregation energies for arsenic atoms and arsenic pairs. It is energetically favorable for an arsenic pair to segregate in the dislocation core, sitting in (2, 3) atomic positions. However, once the arsenic pair is in the dislocation core, it is energetically favorable that this pair dissociates, with the arsenic sitting in (2, 4) positions. Since the two arsenic atoms in the dislocation core are isoelectronic, they repel each other by a Coulomb interaction, lowering the total energy of the system. Fig. 2 shows the total electronic charge distribution for the dislocation containing one arsenic or one arsenic pair in the dislocation core. When arsenic atoms are paired in the dislocation core they keep a reconstruction-like configuration, although they are weakly bonded. This configuration is consistent

Table 1

Total energy change (E_{seg}) in the system for arsenic segregation in the dislocation core, and the distance between arsenic and its first neighbors. The first column shows the position of the arsenic atoms (according to Fig. 1). For a single arsenic, distances (d) are from its first neighbors, while for arsenic pairs distances are between the two arsenic. Energies are given in eV and distances in Å

with arsenic pair segregation in grain boundaries in silicon [23].

In summary, we have investigated the electronic and structural properties of arsenic interaction with the core of a 30° partial dislocation. Our results on segregation towards the 30° partial dislocation is consistent with theoretical investigations on dopant segregation in other extended defects in silicon [3,23,24] and in gallium arsenide [25]. We also find that when an arsenic impurity is near the dislocation core, there is charge transfer from the arsenic to the dislocation, leaving the dislocation core negatively charged [19]. As a result, the dislocation Fermi level is raised by the arsenic presence. Although this is consistent with experimental findings, we still cannot elaborate on the role of this effect in the energetics of kink formation and migration [9].

Modeling the subsurface region of Cz-Si wafers with properly fabricated bulk FZ-Si samples

T. Mchedlidze*, N. Fukata, M. Suezawa

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan

Abstract

Hydrogen and oxygen doped FZ-Si samples with a high concentration of intrinsic defects and contaminant atoms can be considered as a model bulk system for the subsurface device-active region of contemporary Cz-Si wafers. We investigated the creation of vacancy related complexes and the carrier recombination process in such samples using infrared absorption and spin resonance measurement methods. Both the defect creation and carrier recombination processes were found to be affected by the presence of hydrogen or deuterium in the samples. Moreover, we detected an isotopic effect, namely, a significant difference in the influence of hydrogen and deuterium. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si; Vacancies; Hydrogen; Deuterium

1. Introduction

Technological progress has brought about changes in the fabrication of semiconductor devices: the active area of a device persistently ascends towards the surface of Cz-Si wafers. The environment of the wafer subsurface region differs drastically from the bulk: oxygen concentration is significantly reduced due to out-diffusion; concentrations of intrinsic defects (self-interstitials and vacancies) and contaminants are increased. Numerous technological processes, such as dry etching, irradiation, dopant in-diffusion, etc., cause an additional increase in the intrinsic defect concentration and “contamination” of the subsurface region by hydrogen [1,2]. Thus, in the subsurface region, defect formation mechanisms and defect structure may differ significantly from those in the wafer bulk. Investigation of the subsurface region with traditional “volume sensitive” methods (ESR, FT-IR, etc.) can only be done using simulative bulk samples. From the above, it follows that FZ-Si samples doped with oxygen, hydrogen and contaminants and subjected to irradiation can simulate the device-active region.

The effect of hydrogen on the defect creation, structure and properties in Si remains controversial [1–3]. Hydrogen in silicon passivates dopants, dangling bonds and deep level defects, creates various complexes with intrinsic defects, affects oxygen diffusion and thermal donor creation, actively interacts with transition metal atoms, and creates extended electrically active platelet defects. Strong isotope effects connected with hydrogen have also been observed [4–6]. The difference between the strength of Si–H bond and that of Si–D has been proposed as a source of hydrogen isotopic effects [6].

In the present work, we investigated the influence of hydrogen and deuterium doping on the formation of vacancy–oxygen pairs (VO) and divacancies (V_2) and on the carrier recombination processes in the systems modeling the subsurface layer of Cz-Si wafers.

2. Experimental

Starting materials for our investigation were n-type (P-doped, $\rho = 1000$ and $0.6 \Omega \text{cm}$) and p-type (B-doped, $\rho = 1800$ and $1.1 \Omega \text{cm}$) FZ-Si. Sliced samples, mechanically and chemically polished, were annealed at 1200°C

*Corresponding author. fax: +81-22-215-2041.

E-mail address: teimuraz@imr.tohoku.ac.jp (T. Mchedlidze).

for 1 h in quartz capsules filled with H_2 , D_2 or Ar. After the annealing, samples were quenched by immersion in water. Annealed samples were subjected to irradiation with 3-MeV electrons at room temperature (e-irradiation). Total irradiation doses were $d_e = 5 \times 10^{16}$ or $5 \times 10^{17} \text{ e/cm}^2$. After irradiation, the samples were kept at temperatures below -10°C in a refrigerator. Below, we will refer to the samples using three letters indicating conductivity type N or P, resistivity (high—H or low—L) and annealing ambient (argon—A, hydrogen—H, and deuterium—D).

We measured IR absorption in as-grown, annealed and irradiated samples. IR absorption spectra from the specimens $6 \times 6 \times 12 \text{ mm}^3$ in size were measured at 5 K using an FT-IR spectrometer and a continuous helium gas-flow cryostat. The resolution was 0.25 cm^{-1} . Several IR absorption peaks were monitored: that related to interstitial oxygen (O_i), observed at a wavenumber 1136 cm^{-1} , that related to a VO pair, at 835 cm^{-1} [7], that related to V_2 , at 2766 cm^{-1} [8], that related to H_2 , at 3618 cm^{-1} [9], and that related to the H_2^* complex, at 1838 cm^{-1} [10]. The relative intensities of FT-IR absorption peaks were calculated by fitting of the experimental absorption spectra with Lorentzian line-shape peaks. In low resistivity samples, FT-IR measurements were hampered due to a high level of noise from charge carriers.

In the irradiated samples, we measured the ESR signal from the excited triplet state of the VO defect, i.e., the SL1 spectra [11]. The ESR measurements were conducted at 16 K on a JEOL X-band ESR spectrometer using a TM_{011} mode microwave (MW) resonator equipped with a continuous helium gas-flow cryostat. Samples $3 \times 3 \times 12 \text{ mm}^3$ in size were illuminated during measurements through a window in the resonator. The derivative of the MW field absorption with respect to magnetic field was measured using a lock-in amplifier and magnetic field modulation with an amplitude of 0.2 G and a frequency of 100 kHz.

3. Results and discussion

In the present experiments, we did not dope FZ-Si samples with oxygen intentionally. However, unintentional doping of the samples with oxygen and hydrogen occurred from the material of the quartz capsules during high temperature annealing. As a result, O_i concentration in the samples after annealing increased 2–3 times and a H_2 related IR absorption peak appeared even for the samples annealed in argon or deuterium.

Intensities of the FT-IR absorption peaks in various samples after annealing and after subsequent irradiation are presented in Fig. 1. The fitted intensity of each peak was normalized to that of the strongest similar peak in the samples. Error bars in the figure represent the fitting

Fig. 1. Integrated IR absorption peak intensities normalized to that of the strongest similar peak in the samples. (a) O_i related peak before (\circ) and after (\bullet) irradiation; (b) H_2 (\square) and H_2^* (\star) related peaks; (c) VO (\circ) and V_2 (\blacklozenge) related peaks. Lines are presented to guide the eye.

errors of the spectra. After annealing, we detected peaks related to O_i and H_2 (D_2). After irradiation of the samples, O_i , H_2^* , VO and V_2 related peaks were detected. We did not detect a VO related peak in the PL# samples after irradiation due to a high level of noise caused by charge carriers.

The most pronounced effects caused by hydrogen doping and isotopes were observed in the case of VO and V_2 defects. In the case of the NH# samples, hydrogen enhanced V_2 and suppressed VO creation. The effect of deuterium was similar, yet smaller. For the PH# samples, both VO and V_2 creation was enhanced by hydrogen and the effect of deuterium was even stronger in the case of V_2 . Similarly, enhancement caused by deuterium was detected for the V_2 related peak in the PL# samples.

For the samples annealed in hydrogen, the H_2^* related peak intensity was lower in the case of the PLH sample. This effect can be attributed to the lower concentration of the Frenkel pairs in the low resistivity sample during the irradiation [12]. Also, some variations were detected in O_i related peak intensity before irradiation. Interestingly, O_i concentration significantly decreased after irradiation (~ 40 – 50%). Furthermore, no correlation was observed between O_i decrease and VO pair creation. Thus, in addition to the VO pair creation, there would

Fig. 2. Relative intensity of the SL1 signal in various samples after irradiation (○) and normalized ratio of the SL1 signal intensity to that of the VO related FR-IR peak (▼).

seem to be some irradiation or intrinsic defect assisted reaction path, which removes oxygen atoms from interstitial sites.

To avoid possible differences in the Q-factor of the resonator, the amplitude of the SL1 ESR spectra was normalized to the ESR signal from an external standard placed in the resonator. We compared intensity of the ESR and FT-IR signals from the VO complex in high resistivity samples. The results presented in Fig. 2 reveal that the SL1 signal intensity does not follow the VO concentration, but strongly depends on the annealing ambient of the NH# samples.

The SL1 signal arises during the recombination process of the illumination-excited charge carriers through the (VO)* excited triplet state [13]. Thus, the presence of other recombination paths in the sample causes a decrease in the SL1 signal intensity. Simple proof for such a supposition can be obtained from irradiation dose dependence for a normalized ratio of the SL1 signal intensity to that of the VO related FT-IR peak in Cz-Si samples (Fig. 3). The ratio monotonically decreases from unity, starting from the dose $d \cong 2-3 \times 10^{15} \text{ e cm}^{-2}$, showing strong correlation with the creation probability of V_2 . We can suppose that in the case of NH# samples, the increase in the concentration of divacancies for the D_2 and H_2 doped samples may be the reason for the observed decrease in the SL1 spectra intensity.

4. Summary

Significant effects connected with hydrogen doping and isotopes were detected in FZ-Si samples for the creation of VO and V_2 defects under irradiation. The effects depend on the type of conductivity even in the case of high resistivity samples. Enhancement of the

Fig. 3. Irradiation dose dependence for the normalized ratio of the SL1 signal intensity to that of the VO related FT-IR peak in Cz-Si samples. Irradiation was done with 3 MeV electrons at RT.

creation of divacancies and, probably, other recombination active defects causes a decrease in the intensity of the SL1 ESR spectra from the excited triplet state of the VO pair.

Experiments on the FZ-Si samples modeling the subsurface layer of modern materials for device fabrication revealed interesting results. At present, it is too early to speculate about the possible reasons for the observed effects. Further investigation is required to explain the origins of the observed phenomena. It would be interesting to include probable contaminant atoms, such as iron, copper, etc., in the investigation.

Abstract

The formation of radiation defects in Sn-doped Float-Zone (FZ) and Czochralski (Cz) n-type silicon after a high-energy proton irradiation is studied by a combination of Deep Level Transient Spectroscopy (DLTS) and Photoluminescence (PL). Besides the Sn-V levels, evidence is found for at least three new Sn-related radiation defects, two electron traps close to the conduction band and one hole trap close to the valence band. No new PL lines have been identified so far in Sn-doped material. It is furthermore concluded that the Sn-related radiation defects do not show pronounced recombination activity, in the concentration range studied. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Tin vacancy; Proton irradiation; n-type silicon; Deep level transient spectroscopy; Photoluminescence

1. Introduction

It has only recently become clear that the Sn-V complex in irradiated silicon has 4 electronic levels in the band gap: next to the well-known donor levels at 0.066 and 0.317 eV above the valence band [1], two additional acceptor levels have been revealed in irradiated n-type silicon, 0.29 and 0.59 eV below the conduction band [2,3]. This implies that Sn-V is a unique five charge-state centre in silicon. The aim of this paper is to compare the formation of radiation defects in high energy (8 and 60 MeV) proton irradiated n-type Cz and FZ silicon, doped with Sn in the melt to concentrations in the range $\sim 10^{18} \text{ cm}^{-3}$. As reference material, tin-free n-type FZ and Cz silicon has been irradiated, in order to study the impact of Sn-doping on the formation

of cluster damage. DLTS and PL spectroscopy have been applied to investigate the created radiation defects. Beside the Sn-V related deep levels, evidence will be provided for the introduction of other Sn-related defects, at $E_c - 0.074 \text{ eV}$, $E_c - 0.083 \text{ eV}$ and at $E_v + 0.18 \text{ eV}$; their identity will be discussed. From PL at 12 K, further evidence is provided that the presence of Sn reduces the optical recombination activity of radiation defects and defect clusters, compared with tin-free material.

2. Experimental

Details about the samples studied are given in Table 1, indicating that the doping density of all silicon material is about $\sim 10^{14} \text{ cm}^{-3}$ n-type. The Sn-concentration has been measured by SIMS. Standard capacitance DLTS characterisation before and after proton exposure was

n-Cz 6.5×10^{18}	3.14 mm ² Au	1.2	—	61	5.0

performed either on 2 mm diameter Au Schottky barriers or on 1 mm² p-n junctions. The latter have been processed on the tin-free FZ references. In order to reveal the presence of hole traps in the Schottky diodes, an optical injection pulse, generated by a laser diode operating at a wavelength of 895 nm, was used.

Proton irradiations have been performed at different facilities. The 60–61 MeV exposures took place at the Cyclone cyclotron at Louvain-la-Neuve, while the 8 MeV irradiations were done at the TANDEM accelerator at Demokritos in Athens. No bias was applied to the diodes.

Photoluminescence characterisation was performed at 12 K, using carrier excitation by a 488 nm Ar laser, operated at 50 mW power. The Schottky barrier or p-n junction were removed by polishing and etching, in order to have acceptable surface recombination for PL.

3. Results

3.1. Pre-irradiation characterisation

Before irradiation, there are already some deep levels present in the starting material. An example is given in Fig. 1 for Sn-doped FZ and Cz (abbreviated FZ:Sn or Cz:Sn). The dominant peak at about 70 K in Cz:Sn corresponds with the second donor level of the oxygen thermal donors at $E_c - 0.139 \text{ eV}$, as discussed elsewhere [2]. Typical concentrations are in the range of about 10%. It has been shown in addition that there is little interaction with the radiation defects [2]. The apparent activation energies of the other two levels are 0.142 and 0.165 eV; the latter peak could coincide with the V-O or A centre. It is not believed that the as-grown defects are Sn-related as a very similar spectrum has been found for the tin-free Cz reference material. As can be seen from Fig. 1, no deep levels are observed within the sensitivity limits of DLTS above 110 K.

The case is different for the FZ:Sn sample, where three peaks are observed before irradiation. They have apparent activation energy of 0.073, 0.143 and 0.563 eV

Fig. 1. DLT-spectrum of the FZ:Sn and Cz:Sn and the tin-free Cz n-type material. A 1 ms majority carrier pulse from -4 to 0 V was employed.

and appear to be typical for as-grown n-type high-purity FZ silicon [4,5]. Their origin has been discussed elsewhere [6]; briefly speaking, it is assumed that the 0.073 and 0.563 levels are different charge states of a self-interstitial-related defect. The origin of the 0.143 eV peak is unknown. Based on the K_T factor one can rule out the possibility that this level coincides with the $E_c - 0.142 \text{ eV}$ centre in Cz:Sn. The shoulder on the left of the 0.143 eV peak could be C-related [4,5]. In the reference FZ p-n junctions, no deep levels were revealed above the detection limit [7]. In addition, PL analysis before irradiation did not show up specific lines related to Sn. It is, therefore, concluded that Sn-doping by itself does not introduce optical recombination activity, in line with previous reports [8].

3.2. Post-irradiation characterisation

Fig. 2 summarises the 4 cases studied after 60–61 MeV proton irradiation. Beside the as-grown peaks, we can recognise additional deep levels, some of which are well-established from the past. The tin-free references are characterised by the presence of the A-centre and the

Fig. 2. DLT-spectra at 80 Hz after 60 MeV proton irradiation for a Sn-free n-type FZ (a) and Cz (b) sample and for a tin-doped FZ (c) and Cz (d) sample. The radiation fluence was 10^{11} cm^{-2} , except for case d, where the fluence was 5 times higher.

Fig. 3. DLT-spectrum of the n-type Cz:Sn samples before irradiation (Sn2-pre); after a $5 \times 10^{11} \text{ cm}^{-2}$ 61 MeV proton irradiation (Sn1-Irr); after the same irradiation and a 30 min anneal at 80°C under flowing Ar (Sn2-A80C); and for the same irradiation, after a 30 min anneal under Ar at 120°C (Sn2-A120C).

two acceptor states of the divacancy (V-V). The single acceptor has a higher magnitude and is broader than the double acceptor. In addition, the $C_r\text{-}O_i$ hole trap at $E_v + 0.35 \text{ eV}$ is found under minority carrier injection conditions in the FZ and Cz material. The presence of carbon-related radiation defects is also confirmed by the observation of the 0.79 eV C- and the 0.97 eV G-line in PL [6,7,9].

In the Sn-doped samples, at least four additional electron traps can be observed in Fig. 2 or 3, two of which have been discussed in detail before [2,3]. They are ascribed to the single and double acceptor state of

the Sn-V. Furthermore, two shallow electron traps are found at $E_c - 0.074$ and 0.083 eV , which have only been observed in irradiated Sn-doped material (Fig. 3). As can be derived from Figs. 2 and 3, they occur both in Cz or FZ material, so that a correlation with oxygen is rather unlikely. They are, therefore, tentatively identified as Sn-related radiation defects. Similar shallow levels have been reported before in neutron-irradiated n-type FZ:Sn [10].

Fig. 3 shows spectra obtained after 60 MeV proton irradiation and annealing for 30 min at 80 or 120°C , for the Cz:Sn samples. No results are available for the FZ:Sn yet. It has been demonstrated that the Sn-V dissociates below 120°C for $\sim 10^{14} \text{ cm}^{-3}$ doped n-type material [2], which was lower than previously reported for p-type silicon [1] or for higher doped n-type Si [11,12]. According to Fig. 3, the shallowest level (0.074 eV) also disappears at or below 120°C , while the second peak (0.083 eV) is still observed—even seems to grow—after 120°C annealing. It is too early to come up with a definitive identification of these unknown centres, but at least the second peak is a candidate for one of the higher order Sn_mV_n defects, recently identified by EPR [13] and showing a higher thermal stability than Sn-V. A more systematic annealing study is required to further establish the nature of the peaks.

As reported elsewhere [6], in the 8 MeV proton-irradiated FZ:Sn sample, an unknown hole trap at $E_v + 0.18 \text{ eV}$ has been found as well. It is also tentatively assigned to a higher-order tin-vacancy complex. According to ab initio calculations, SnV_2 or Sn_2V_2 should have levels in both parts of the band gap [14], which could be well in line with the present observations.

Finally, Fig. 4 compares the PL spectrum before and after 60 MeV proton irradiation for a tin-doped FZ sample. On top of the phosphorus-related excitonic

Fig. 4. PL spectra of a $\sim 10^{18} \text{ cm}^{-3}$ Sn-doped n-type FZ sample before (solid line) and after (dashed line) a 10^{11} cm^{-2} 60 MeV proton irradiation.

luminescence, additional lines are found, which have been identified as C-related radiation defects [7,9]. Qualitatively similar spectra are observed in the tin-free reference material [6]. This indicates that the Sn-V centres do not exhibit optical recombination activity.

4. Discussion

Summarising the above findings, it is clear that Sn-doped n-type silicon shows up a whole set of new radiation defects, which may affect the electrical properties, like the recombination or generation lifetime. The electronic characteristics of the Sn-V centre are now fairly well understood, both from an experimental and a theoretical viewpoint, but the search for the higher order tin-vacancy complexes is ongoing. It is also clear from comparing the FZ and Cz material that there seems to be little direct interaction between the formation of Sn-related radiation defects and interstitial oxygen.

It has been reported on several occasions that the trapping-ability of substitutional tin may help in controlling/suppressing the formation of detrimental radiation defects like the A- and E-centre or V-V [1,2,11,12]. A reduction of the trap introduction rate by a factor 3 for the $5 \times 10^{11} \text{ cm}^{-2}$ 60 MeV proton irradiations studied here (Cz:Sn), up to a factor 10 for 2 MeV electron irradiations have been reported [2,11,12]. However, this occurs at the cost of the creation of additional Sn_mV_n complexes, which in the end may result in a higher device degradation. However, for the conditions studied here, it is concluded that the optical recombination properties are better preserved in Sn-doped FZ silicon compared with the reference material [6]. In addition, preliminary recombination lifetime measurements of γ -irradiated Sn-doped Cz silicon confirm the better radiation resistance, for a Sn concentration in the range $\sim 10^{18} \text{ cm}^{-3}$ [15]. On the other hand, little or no improvement has been observed for $6.5 \times 10^{18} \text{ cm}^{-3}$ Sn-doping, suggesting that there

exists a delicate balance between the suppression of the harmful radiation defects on the one hand and the electrical activity of the additional Sn_mV_n centres on the other.

5. Conclusions

The formation of proton-irradiation defects in n-type Sn-doped Cz and FZ silicon has been compared. It was observed that the same types of defects are formed. Next to the Sn-V pairs, it is believed that two additional electron and one extra hole trap are created in Si:Sn. From the PL results, it is concluded that Sn or Sn-V do not introduce new lines. In spite of its four levels in the band gap, Sn-V is found to be not particularly recombination active compared with the standard radiation defects.

Interface strain in thermal Si/SiO₂ analysed by frequency-dependent electron spin resonance

Dieter Pierreux*, André Stesmans

Departement Natuurkunde, Katholieke Universiteit Leuven, Celestijnenlaan 200D, 3001 Leuven, Belgium

Abstract

Thermal oxidation of Si gives intrinsically rise to the generation of Si dangling bond type defects at the Si/SiO₂ interface. In standard (1 1 1)Si/SiO₂ the dominant one observed by electron spin resonance (ESR) is the P_b (Si₃≡Si•) center. It is generally accepted that the driving agent for these defects is the occurrence of interfacial strain. A frequency dependent ESR study on these P_b defects has enabled the separation of the strain broadening component from other line broadening mechanisms, leading to a direct quantification of the associated interface stress. This resulted in the observation of thermal treatment induced variations in the strain broadening contribution indicating the existence of two different interfacial relaxation processes. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Si/SiO₂ interface; Defect; ESR; Strain

1. Introduction

Several studies have reported on the observation of an intrinsic SiO₂ film stress resulting from thermal oxidation of Si [1–4]. The origin of this stress has been attributed to the 120% molar volume expansion which results from the conversion of Si to SiO₂. As a result of this mismatch induced stress, dangling bond type defects are generated at the interface. In standard thermal (1 1 1)Si/SiO₂ the dominant paramagnetic interface defect observed by electron spin resonance (ESR) is the P_b center—interfacial (Si₃≡Si•) [5]. In the as-grown state, a P_b density of $\sim 4.9 \times 10^{12} \text{ cm}^{-2}$ is inherently incorporated for the oxidation range 300–950°C. This value appears strongly correlated with the constant interfacial intrinsic stress [6]. It is generally accepted that P_b defects occur at the interface to (partly) alleviate interfacial stress. Despite their generally malignant character, these defects, as sensed by ESR, may serve as sensitive probes for interface characterization. For one, the interface strain was formerly quantified in

terms of their *g*-factor distribution inferred from the magnetic field angle dependence of the ESR line width [6–8]. However, for larger areal defect densities, that method becomes unsuitable by interference of anisotropic two-dimensional dipolar broadening [9]; an extensive parameterised global fitting procedure is required to enable extraction of both anisotropic contributions.

In the present work this has been overcome by carrying out a detailed study of the P_b ESR properties as a function of the resonance frequency (X, K and Q band). This has enabled the separation of the strain broadening component from the dipolar one.

2. Experimental details

Sample slices (2 × 9 mm²), appropriate for ESR, were cut from 2-in diam. two-side polished (1 1 1) Si wafers (float zone; >100 Ω cm; p-type; thickness ~70 μm). After cleaning, the slices were thermally oxidised in a high-vacuum laboratory facility at *T*_{ox} ~ 970°C (1 atm, 99.9995% dry O₂) for ~1 h (*d*_{ox} ~ 56 nm), terminated by cooling to room temperature in O₂ ambient (time constant ~200 s). Subsequently, a first ESR sample

*Corresponding author. Tel.: +32-16-327-679; fax: +32-16-327-987.

E-mail address: dieter.pierreux@fys.kuleuven.ac.be (D. Pierreux).

was submitted to a post oxidation anneal (POA) in H_2 (1 atm, 99.9999%) for ~ 1 h at 780°C to enhance P_b density. Yet, as all P_b -defects are then automatically left passivated by H this was followed by a P_bH dissociation step in order to ESR-activate the defects, i.e., vacuum annealing ($< 4 \times 10^{-7}$ Torr) at 605°C for ~ 1 h. A second sample received a POA in vacuum (POVA) at 1200°C for 37 min. A third sample, not submitted to any postoxidation thermal treatment, served as a reference. Conventional absorption-derivative X, K and Q band ESR-observations were made at 4.3 K.

3. Experimental results and discussion

3.1. As-oxidised (111)Si/SiO₂

Fig. 1 illustrates the influence of the resonance frequency ν on the P_b ESR signal, which will be analysed below.

The measured first derivative peak-to-peak linewidth ΔB_{pp}^T as a function of ν is shown in Fig. 2 for three values of φ_B , the angle between the applied magnetic field \mathbf{B} and the interface normal \mathbf{n} . A general increase in ΔB_{pp}^T with increasing ν and φ_B is clearly observed.

From φ_B -dependent observations, previous studies had concluded that the P_b ESR line width in standard (111)Si/SiO₂ consists of mainly two superimposed contributions [7,8]: In addition to an angle independent residual part, there is a considerable (supposedly) Gaussian type broadening monotonically growing for $\varphi_B \rightarrow 90^\circ$. The latter is attributed to strain-induced variations in the g tensor, predominantly in g_\perp . Underlying insight was provided by the work of Watkins and Corbett [7,10]. The supposedly Lorentzian residual linewidth contribution was mainly attributed to unresolved ^{29}Si superhyperfine broadening [7]. A later, more in-depth study of the residual line shape for $\mathbf{B} \parallel \mathbf{n}$

Fig. 1. Influence of resonance frequency ν on P_b ESR signal for the as-grown thermal Si/SiO₂ interface with $[P_b] \sim 5 \times 10^{12} \text{ cm}^{-2}$. For each ν , spectra for two directions of \mathbf{B} are shown: Solid lines: $\mathbf{B} \perp (111)$; Dotted lines: $\mathbf{B} \parallel (111)$.

Fig. 2. Frequency dependence of the P_b ESR peak-to-peak line width of the as-grown reference sample for different orientations of \mathbf{B} : $\varphi_B = 0^\circ$ (\square), $\varphi_B = 45^\circ$ (\triangle), $\varphi_B = 90^\circ$ (\diamond).

interface revealed clearly the influence of a P_b -density dependent dipolar broadening [11].

As mentioned, it is our aim to quantify the interface strain in terms of the P_b g -factor distribution from frequency dependent measurements instead of the formerly φ_B dependence of ΔB_{pp}^T . Two approximations are made: first, it is assumed that the frequency independent part, mainly consisting of ^{29}Si superhyperfine and dipolar broadening is purely Lorentzian and void of strain; Second, the strain component ΔB_{pp}^{SB} can be related to Gaussian distributions in g and g_\perp with standard deviations σg and σg_\perp , respectively. To a first approximation, the frequency dependence of ΔB_{pp}^{SB} can then be expressed as

$$\Delta B_{pp}^{SB} = \frac{2h\nu}{\beta} \left(\frac{g \cos^2 \varphi_B}{g^3} \sigma g + \frac{g_\perp \sin^2 \varphi_B}{g^3} \sigma g_\perp \right). \quad (1)$$

This is a generalized approach of the one presented in Ref. [7] where $\sigma g = 0$ was assumed. The g map for rotation of \mathbf{B} from $\mathbf{B} \parallel \mathbf{n}$ ($\varphi_B = 0^\circ$) towards $\mathbf{B} \perp \mathbf{n}$ ($\varphi_B = 90^\circ$) contains one single branch, obeying

$$g = \sqrt{(g \cos \varphi_B)^2 + (g_\perp \sin \varphi_B)^2}, \quad (2)$$

with principal values inferred as $g = 2.00136 \pm 0.00003$ [6] and $g_\perp = 2.0088 \pm 0.0001$. The measured convolution of the frequency independent Lorentzian part and the Gaussian strain component is expected to be largely Voigt-like. The measured width ΔB_{pp}^T is then expected to be adequately described by

$$\Delta B_{pp}^T = \frac{1}{2} \Delta B_{pp}^L + \left((\Delta B_{pp}^G)^2 + \frac{1}{4} (\Delta B_{pp}^L)^2 \right)^{1/2}, \quad (3)$$

where ΔB_{pp}^L and ΔB_{pp}^G represent the Lorentzian and Gaussian linewidths of the Voigt shape. After inserting Eq. (2) for g in Eq. (1) and substituting Eq. (1) for ΔB_{pp}^{SB} ,

the curves in Fig. 2 are obtained as optimised least-squares-fits of Eq. (3) to the ΔB_{pp}^T -vs- ν data.

For $\mathbf{B} \perp (111)$, this resulted in $\Delta B_{pp}^L = 1.55 \pm 0.05$ and $\sigma g_{\parallel} = 0.00014 \pm 0.00001$, where the inferred value of σg_{\parallel} is found to be in good agreement with previously reported values [6,9] ($\sigma g_{\parallel} = 0.00015$). Here, it should be added that the reported value of $\sigma g_{\parallel} = 0.00032$ [6] was obtained by assuming a half Gaussian distribution to simulate the apparent asymmetry of the P_b -signal; when applying a full Gaussian distribution an extra factor ~ 2 needs to be taken into account. The obtained ΔB_{pp}^L can be read at the intercept of the ΔB_{pp}^T -axis as a direct result of the assumption that the Lorentzian part is frequency independent; Indeed, according to Eq. (3), $\Delta B_{pp}^T = \Delta B_{pp}^L$ for $\nu = 0$. This remaining component, void of strain, represents the residual line width composed of the intrinsic part $\Delta B_{pp}^{\text{int}}$ (mainly ascribed to unresolved ^{29}Si superhyperfine) and dipolar broadening $\Delta B_{pp}^{\text{dip}}$. The latter are separated using the Lorentzian addition rule $\Delta B_{pp}^L = \Delta B_{pp}^{\text{int}} + \Delta B_{pp}^{\text{dip}}$. From a former study [11], analysing the ESR line width (for $\mathbf{B} \parallel \mathbf{n}$) as a function of the $[P_b]$, the value $\Delta B_{pp}^{\text{int}} = 0.4 \text{ G}$ is inferred for $[P_b] \sim 5 \times 10^{12} \text{ cm}^{-2}$, from where $\Delta B_{pp}^{\text{int}} \sim 1.15 \text{ G}$. This emerging constant value may be compared with the reported value of $\Delta B_{pp}^R = 1.29 \pm 0.03 \text{ G}$ [11], deduced by extrapolation of the $\Delta B_{pp}^T(\mathbf{B} \parallel \mathbf{n}) - f$ relationship towards $f \rightarrow 0$, where f represents the defect concentration, to eliminate the dipolar contribution. The small deviation arises from the existence of a small σg_{\parallel} [6], not separated by extrapolation to $f \rightarrow 0$.

The σg_{\perp} value was derived for two field directions \mathbf{B} ($\varphi_B = 45^\circ, 90^\circ$; cf. Fig. 1) with σg_{\parallel} and ΔB_{pp}^L kept fixed at the values inferred from the fit for $\varphi_B = 0^\circ$, and varying only σg_{\perp} ; keeping ΔB_{pp}^L fixed is justified by the small anisotropic dipolar broadening for the present defect densities. The inferred value $\sigma g_{\perp} = 0.00076 \pm 0.00002$ is in good agreement with the previous values ($\sigma g_{\perp} = 0.00078; 0.00080$) [7,8]. The agreement of the obtained parameters substantiates the previous angle dependent method.

3.2. Thermal treatment

The measured P_b line widths for the samples subjected to postoxidation treatment are shown in Fig. 3. From optimised fitting along the lines outlined above two features become clear: While the σg_{\parallel} -value stays fixed at 0.00014, yet, there is an obvious decrease in the σg_{\perp} , i.e., 0.00046 ± 0.0002 for POVA and 0.00058 ± 0.0002 for POA (H_2). The unaltered value of σg_{\parallel} may be attributed to the inherently smaller sensitivity of g_{\parallel} to strain or, in a different point of view, might just indicate the residual spread on g_{\parallel} to be of a different nature. Yet, the remarkable drop in σg_{\perp} occurring after postoxidation treatment indicates the occurrence of stress relaxation at the Si/SiO₂ interface.

Fig. 3. Frequency dependence of the P_b ESR peak-to-peak line width of samples subjected to postoxidation thermal treatment: POVA (\circ), POA H_2 (∇). Solid and dotted lines represent least-squares fits using Eq. (3) for $\varphi_B = 90^\circ$ and $\varphi_B = 0^\circ$, respectively. For comparison, the data of the reference sample for $\varphi_B = 90^\circ$ (\diamond) (dashed curve fit) are also shown (see also Fig. 1).

A last item to be addressed in Fig. 3 is the larger $\Delta B_{pp}^T(\nu \rightarrow 0)$ value for the thermal treated samples as compared to the reference sample. This is ascribed to enhanced dipolar interactions due to strongly increased defect densities as a result of PO annealing of the Si/SiO₂ interface [12,13], determined as $\sim 2 \times 10^{13} \text{ cm}^{-2}$ and $\sim 3.4 \times 10^{13} \text{ cm}^{-2}$ for POVA and POA H_2 respectively. Indeed, a φ_B map of the ΔB_{pp}^T vs φ_B now clearly reveals anisotropic dipolar broadening.

4. Interpretation

According to the simple Maxwell viscoelastic model of a solid, stress relaxation occurs by viscous motion of a-SiO₂ material away from the growth interface. If assuming the rate of stress relief to be proportional to the stress (as is usually the case) then

$$\frac{d\sigma_i}{dt} = -\frac{\sigma_i}{\Gamma}, \quad (6)$$

where Γ is a constant, namely the viscoelastic relaxation time; σ_i is the intrinsic growth stress, i.e., the stress that is generated through the film growth process. From integrating Eq. (6), one obtains the expression $\sigma_i(t) = \sigma_i(0) \exp(-t/\Gamma)$ for the stress relief process where $\sigma_i(0)$ is the maximum intrinsic stress at the growth interface and t the oxidation or annealing time.

For the reference sample, the outer surface of the growing Si/SiO₂ film has been annealed at T_{ox} for the entire period of oxidation, whereas little so for oxide at the final interface. In consequence, virtually no stress relaxation via viscous flow has occurred for the interface region leading to a highly stressed interface. This is

mirrored in σg_{\perp} : the in-plane stress leads to variations in the defect's local environment over the interface resulting in slightly different g -tensors.

Within this model, the POVA results become clear, i.e. without further oxidising flux, the interface has the possibility to relieve stress during 37' at 1200°C. At this temperature the viscoelastic relaxation time Γ is small [14] and an efficient relaxation can occur. The less strained interface gives rise to smaller local defect environment variations leading to a lower σg_{\perp} . On the microscopic level, at the high anneal temperature, the interface may rearrange interfacial bonds and angles to attain a lower energetic state.

Former stress data show that almost no (viscoelastic) relaxation can occur during film growth or annealing for temperatures below 800°C [6,14]. The key point is that annealing at high temperature ($T_{\text{an}} > 950^{\circ}\text{C}$) represents a condition where Γ is comparable to, or shorter than, annealing time t_{an} , whereas for $T_{\text{an}} \leq 800^{\circ}\text{C}$, Γ is at least an order of magnitude larger than t_{an} . Consequently, the relaxation that occurs after POA in H_2 at 780°C is likely from another origin. The fit result for the latter sample can be consistently interpreted within the understanding of the defect-strain relationship: Defects are created to alleviate interfacial stress [6]. It was formerly observed that one effect of H_2 POA is an irreversible interfacial bond rupture, yielding additional defects indistinguishable from the pre-existing P_b defects [13]. Thus, the system may locally release stress associated energy through defect creation, thus locally relaxing the interface. At high defect densities, as in the present case, the local relaxation can become more global by percolation, leading to a generally lower intrinsic interface strain, reflected in the lower σg_{\perp} .

5. Conclusions

A frequency-dependent ESR study of the P_b defect has enabled to quantify the interface stress at the

(111)Si/SiO₂ interface. In contrast with field angle dependent results, which are complicated by the interference of anisotropic dipolar broadening at higher defect densities, this method is generally applicable.

For standard thermal (111)Si/SiO₂ the inferred values $\sigma g = 0.00014$ and $\sigma g_{\perp} = 0.00076$ are in good agreement with previous field angle dependent results, confirming the previous insight in the constituent line broadening mechanisms.

In a study of the effect of postoxidation thermal treatments a marked influence on the strain broadening component is revealed, indicating the existence of two different interface relaxation processes: i.e., relaxation of interfacial stress through bond length and angles adjustment (in nonoxidising ambient) or interface defect creation.

$C-V$ and $G-V$ characterization of defects in ultrathin SiO_2 thermally grown on RF plasma-hydrogenated silicon

S. Alexandrova^{a,*}, A. Szekeres^a, E. Halova^b^a *Institute of Solid State Physics, 72 Tzarigradsko Chaussee, Sofia 1784, Bulgaria*^b *Technical University, 8 Kl. Ohridski Blvd., Sofia 1797, Bulgaria*

Abstract

In the present study, results on the interface properties of ultrathin SiO_2 thermally grown on RF plasma-hydrogenated silicon structures are reported from a detailed study of the $C-V$ and $G-V$ characteristics taken at various frequencies. From frequency characterization, information is gained on the charged defects at the Si/SiO_2 interface. The frequency dispersion properties reveal the presence of either interface traps or laterally inhomogeneous distribution of defect centers within the oxide near the interface Si/SiO_2 . The amount and nature of the defects depend on the substrate temperature during plasma exposure. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

Silicon surface cleaning before thermal oxidation is an essential step in the whole cycle of the fabrication of metal-oxide-Si (MOS)-based devices, especially in the deep submicron technological era. In recent years, this processing step has gained increased attention. Different techniques have been tested to obtain a stable and well-controlled surface, e.g. frozen gas bombardment [1] and organic contamination removal by UV/ozone [2]. Recently, we have suggested a RF hydrogen plasma treatment as a Si pre-oxidation cleaning procedure [3]. The fast initial oxide growth observed in this case would allow a better control of low-temperature oxidation at technologically reasonable times. The oxidation kinetics analysis has shown the formation of a defective surface overlayer, whose density is reduced by voids formation, left after the hydrogen plasma cleaning.

In the present study, results on the interface properties of the MOS structures with ultrathin SiO_2 grown thermally over hydrogenated silicon are reported from

a detailed study of the $C-V$ and $G-V$ characteristics at different frequencies between 10 kHz and 1 MHz. From the frequency characterization, information is gained on the charged defects at the Si/SiO_2 interface.

2. Experimental

In this study, the oxides were thermally grown to a thickness of about 13 nm in dry O_2 at a temperature of 850°C. The bare n-type (111)-oriented Si wafers of 5–10 Ωcm resistivity were initially treated by a typical wet RCA pre-gate oxide clean [4]. Shortly after cleaning, some of the wafers received dry cleaning by exposure to hydrogen plasma in a RF planar unit located on the lower grounded plate. The wafers were plasma treated with or without heating to 300°C. The gas pressure was 1 Torr; the input power at 13.56 MHz was 15 W. Some of the wafers were given an RCA clean only to serve as references.

For the electrical characterization, MOS capacitors were formed by vacuum evaporation of aluminum dots onto the thermally grown oxides followed by backside metallization.

The $C-V$ and $G-V$ measurements were performed at room temperature in the frequency range 10 kHz–1 MHz. The measurement unit was a Precision Component Analyzer WAYNE KERR 6425.

3. Results and discussion

Fig. 1 gives the high frequency (10–200 kHz) $C-V$ characteristics of the MOS capacitors with oxides grown on RF plasma hydrogenated (111)Si. In this case, the silicon substrate was not heated during plasma hydrogenation. The $C-V$ characteristics show frequency dispersion. In the depletion region for a given gate voltage the capacitance increases with measurement frequency due to the time-dependent response of interface states. In accumulation no appreciable frequency dispersion is evident in this frequency range. At higher frequencies up to 1 MHz frequency dispersion related to the contribution of series resistance by the substrate was observed (not shown in Fig. 1) [5]. Because of this, the oxide capacitance was calculated from the MOS capacitance of the 10 kHz $C-V$ curve in strong accumulation, where the series resistance contribution is negligibly small. This value has been used further throughout the study for estimation of the defect concentrations.

The $G-V$ characteristics of the MOS capacitors are plotted in Fig. 2 for the same frequency interval. The conductance was found to increase with increasing measurement frequency.

Fig. 1. Frequency dispersion of the $C-V$ curves of MOS capacitors with SiO_2 grown on (111)Si substrate hydrogenated in RF plasma without heating.

In Figs. 3 and 4 $C-V$ and $G-V$ characteristics of the MOS capacitors with Si substrates hydrogenated at a temperature of 300°C are displayed. Comparison with the results in Figs. 1 and 2 shows that silicon hydrogenation temperature plays an important role for the interface quality. At 300°C the $C-V$ curves shift to more positive voltages and shows much less frequency dispersion. The conductance peaks are substantially smaller. These results, indicating reduction in interface defect concentrations, can evidently be attributed to thermal annealing effect.

The specific shape of the $C-V$ curves as seen in Figs. 1 and 3 could also be indicative of nonhomogeneous distribution of the oxide charges [5].

The defect concentrations related to so-called fixed oxide charge and interface traps have been derived from the frequency dispersions of the $C-V$ and $G-V$ characteristics. The results are summarized in Table 1 where the concentrations of the reference oxides are also presented for comparative purposes.

The fixed oxide charge has been obtained from the difference between the experimental and theoretical flatband voltage and the values are given in Table 1. To obtain a more realistic estimation of the fixed oxide charge independent of the contribution of interface trap charge, an approximation approach has been applied based on simple high-frequency analysis of the $C-V$ frequency dispersion [6]. The approach requires examination of the linear dependence of the flatband voltages on logarithm of the measurement frequency. This linear relationship is displayed in Fig. 5 for two capacitors with silicon hydrogenated at two different temperatures. The

Fig. 4. Frequency dispersion of the $G-V$ characteristics of MOS capacitors with SiO_2 grown on (111)Si substrate hydrogenated in RF plasma at 300°C.

voltage V_f obtained from the interception of the two straight lines characterizes the intrinsic oxide charge $Q_f = C_{ox} V_f$ and amounts to $2.4 \times 10^{12} \text{ cm}^{-2}$. This charge can be regarded as inherent to the hydrogenated oxides. The variations observed in the fixed oxide concentration through the $C-V$ shifts are most probably related to charge located in interface traps.

From Fig. 5 it can also be inferred that the frequency dispersion is more pronounced for lower hydrogenation temperature of the silicon, indicating higher overall density of defect centers.

Using the single-frequency approximation method developed in Ref. [7] the density of interface traps has been calculated. The results are presented in Table 1. It can be seen from the Table that the interface trap density, compared with the reference RCA silicon, is high for the silicon hydrogenated without heating and is reduced in silicon hydrogenated at elevated temperature (300°C). The higher density in the former case can be attributed to defects introduced by the plasma treatment during hydrogenation, which persist after oxidation. Formation of voids on silicon surfaces exposed to hydrogen plasma has been reported elsewhere [8]. The increase of the temperature up to 300°C seems to reduce the concentration of these surface defects. The concentration of the interface trap defect centers is consequently reduced to a level even below that of the reference MOS capacitor.

4. Conclusion

The electrical characterization of ultrathin (13 nm) SiO_2 , thermally grown on hydrogenated (111) silicon has revealed large interface defect densities (fixed oxide charge and interface traps) when hydrogenation has been performed without substrate heating. This is attributed to formation of defects on the Si surface. Increasing the temperature during hydrogenation results in lower defect densities ($1.7 \times 10^{11} \text{ eV}^{-1} \text{ cm}^{-2}$ and

Table 1

The interface defect densities of the Si/SiO₂ structures as obtained from *C–V* and *G–V* measurements

Si-substrate preparation	Fixed oxide charge (10^{12} cm^{-2})	Interface trap density ($10^{11} \text{ eV}^{-1} \text{ cm}^{-2}$)
Hydrogenated, without heating	4.8	20
Hydrogenated at 300°C	3.1	1.7
RCA	3.5	6.8

$3 \times 10^{12} \text{ cm}^{-2}$ for the interface traps and fixed oxide charge, respectively). The density of interface traps is decreased considerably in comparison to the standard RCA cleaned silicon. The reduction of the fixed oxide charge is apparently due to the contribution of charge trapped in interface states. An inherent fixed oxide charge value is evaluated ($\sim 2.4 \times 10^{12} \text{ cm}^{-2}$) from a high frequency *C–V* approximation.

Abstract

We carried out a theoretical investigation on the properties of antiphase defects, or core reconstruction defects, in a 30° partial dislocation in Si and GaAs. The calculations were performed using ab initio total energy methods, based on the density functional theory. From the results on formation energies of these reconstruction defects, we predict that the concentration of dislocation-related electrically active centers should be considerably larger in GaAs than in Si. We also find that an antiphase defect in silicon may exist in positive, neutral, or negative charge states, with a Mott–Hubbard potential of 0.30 eV. © 2001 Elsevier Science B.V. Keywords: Extended defects; Point defects; Dislocations

1. Introduction

Dislocation motion is known to control the plasticity of materials. In semiconductors, they also affect the electronic properties by generating energy levels in the materials gap. As a result of the current requirements for device miniaturization, the physical properties of dislocations have attracted considerable interest over the last few years [1,2]. More recently, macroscopic properties of dislocations were found to be directly correlated to the atomistic events which occur inside the dislocation core [3–5]. In such a scenario, understanding the dislocation core properties became fundamental in order to develop better electronic devices. Here, we present a theoretical investigation on the structural and electronic properties of reconstruction defects which may form in the core of a 30° partial dislocation in silicon and in gallium arsenide.

In zinc-blende semiconductors, dislocations are generally confined to the {111} glide sets [6]. As a result of the strong covalent bonding, they are aligned along

$\langle 110 \rangle$ directions. It is energetically favorable for (screw and 60°) dislocations to dissociate into (30° and 90°) partial dislocations, with a stacking fault connecting the partials. In a III–V compound, such as gallium arsenide, dissociation may generate three types of dislocations: α , consisting of a 30° plus a 90° partial with the cores formed by type-V atoms; β , consisting of a 30° plus a 90° partial with the cores formed by type-III atoms; and a screw dislocation, consisting of two 30° partials, one of each type. In a type-IV semiconductor, α and β dislocations are identical. Here, we have focused our investigation on the 30° (α and β) partial dislocations because of their controlling role on the mobility of both 60° and screw dislocations [7].

Dislocations should generate a large number of electrically active centers, as a result of undercoordinated atoms in the dislocation core. Experimental data indicated otherwise, showing that semiconducting materials have low concentrations of dislocation-related active centers [8,9]. To overcome this apparent controversy, a model has been suggested in which atoms in the dislocation core recover their fourfold coordination by reconstruction, forming intra-core bonds [10]. Recent investigations have shown that core reconstruction of partial dislocations is, in fact, energetically favorable

Fig. 1. Atomic configuration in a $\{111\}$ glide plane, with a 30° partial dislocation dipole lying along a $\langle 110 \rangle$ direction. The figure shows the α and β dislocations (a) with the reconstructed core, (b) with two α -APDs, and (c) with two β -APDs. Large and small circles represent atoms in the top (type V atoms) or in the bottom (type III atoms) of the glide plane, respectively. The figure only shows the intra-plane glide bonds.

[5,11]. Fig. 1a shows a $\{111\}$ glide plane containing the reconstructed cores of an α and a β 30° partial dislocation. Although core reconstruction is energetically favorable, it is still possible that a few of the core atoms remain unreconstructed at finite temperatures (Fig. 1b and c). These centers are called antiphase defects (APD), or reconstruction defects, and may generate electrically active centers in the gap of the material. Here, we have defined the α -APD and the β -APD as the reconstructed defects, respectively, in α and β dislocations in a III–V compound.

2. Theoretical model

Our calculations were performed using ab initio total energy methods. We considered a reference orthorhombic supercell with 288 atoms, in which a 30° partial dislocation dipole was introduced. The dislocation dipole contained an α and a β partial dislocation in GaAs, or two identical partials in Si. For the configurations presented in Fig. 1, an atomistic simulation based on ab initio methods is a formidable computational task. In order to perform such calculations, we initially relaxed the structures with a less expensive model, using an interatomic potential [12,13]. In such calculations, the shape of the super-cells was adjusted using the Parrinello–Rahman method [14], and therefore removing the internal stress generated by the dislocations. The output atomic configurations were used as input to the ab initio calculations, when full relaxation was finally performed. This two-step procedure can considerably reduce the computational cost in finding the equilibrium configurations, specially in the case of dislocations [15]. The ab initio [16] calculations were performed using the density functional theory in the local density approximation. The Kohn–Sham equations were solved by the Car–Parrinello scheme with norm-conserving pseudopotentials [17,18]. The electro-

nic wave functions were expanded in a plane-wave basis-set, with kinetic energy up to 10 Ry. The Brillouin zone was sampled by a set of two representative k -points [19]. These k -points were related to the dislocation line direction [5,20]. Geometric optimization of the atomic structures was performed by allowing atoms to relax until the Hellmann–Feynman forces were smaller than $0.02 \text{ eV}/\text{\AA}$.

3. Results and Discussions

Core reconstruction controls dislocation mobility, for example, activation energy for dislocation velocity scales with the core reconstruction energy [5,21]. From our calculations, we found that core reconstruction energy, or the energy required to break a core bond, is much larger for dislocations in Si than for α or β dislocations in GaAs. We found a reconstruction energy of 0.92 eV for a 30° partial dislocation in Si, while it is, respectively, 0.43 and 0.56 eV for $30^\circ\alpha$ and β partials in GaAs. Such a wide range of reconstructions energies is because reconstruction involves bonding between atoms of the same species. As a result, there is an additional electrostatic repulsion between the core atoms in GaAs as compared to Si, but still not strong enough to prevent core reconstruction. Bonds inside the dislocation core ranged from 2.27 to 2.49 \AA in Si, from 2.34 to 2.57 \AA in the α dislocation, and from 2.33 to 2.47 \AA in the β dislocation. For the bonds involved in the reconstructed core in silicon, angular distribution between bonds ranged from 92° to 124° , with an average of 108.8° . Several angles in the dislocation core were far away from the typical tetrahedral angle (109.47°). This may explain why even the reconstructed core generates energy levels in the materials gap [5].

We now consider the properties of the antiphase defects in Si and GaAs. In silicon, the APD formation energy is 0.82 eV . This value is in good agreement with another recent theoretical investigation [20], which found $(0.65 \pm 0.2) \text{ eV}$. It should be pointed out that the latter investigation [20] considered an artifact to use smaller simulations cells, which have compromised their result. From our results, the concentration of APDs in the dislocation core ($\rho = e^{-E_{\text{apd}}/k_B T}$) would be 10^{-5} of the atomic core sites at $T = 900 \text{ K}$. This value is consistent with experimental results on the concentration of electrically active centers in deformed silicon [8].

In the case of GaAs, formation energies are 0.36 and 0.44 eV for α -APD and β -APD, respectively. In both Si and GaAs, the APD energy scales with the respective core reconstruction energy, being around 80% of that energy. This provides a very good agreement with a recent model, in which it was suggested that dislocation activation energies scale with the dislocation core reconstruction energies [5]. With these low formation

energies of α and β -APDs, the concentration of electrically active centers should be considerably larger in deformed GaAs than in deformed Si. The bonds in an APD are considerably different from those in a reconstructed atom. In both Si and GaAs, we observed that the three respective neighboring atoms of an APD relax inward and form a near planar structure, with an average angle of 118° .

We additionally studied the electronic properties of the dislocation core in silicon, as shown in Fig. 2. As has been recently investigated, the unreconstructed core generates a half-filled one-dimensional band in the materials gap [5]. For the reconstructed core, this one-dimensional band splits up into a filled bonding and an empty antibonding state. On the other hand, an APD generates a bonding and an antibonding level inside the materials gap. The APD bonding level will be near the top of the dislocation-related bonding band, while the APD antibonding level would be at the bottom of the dislocation-related antibonding band.

The APD in silicon can stay in different charge states, depending on the position of the Fermi energy level. Here, the simulations were performed by removing (or inserting) two electrons in the system, and allowing all the atoms to relax. As shown in Figs. 1b or c, there were always two APDs in the simulation cells. Since these two APDs in each cell give degenerated energy levels in the materials gap, then by removing (or inserting) two electrons we could investigate the $+1$ (or -1) charge state of an individual APD. In order to understand the effects of an APD on the electronic conductivity of a deformed material, we searched for some electronic

charge trapping center resulting from the APD presence. For that, we computed the Mott–Hubbard potential (U) using the total energies of the system with the APD in neutral, positive and negative charge states. In the case of an APD in silicon, we found a positive $U = 0.30$ eV. This large Mott–Hubbard potential means that it is not energetically favorable for the APD in its neutral state to spontaneously capture an additional electron. Therefore, the APDs should be electrically active, being detectable by electron paramagnetic resonance (EPR) measurements.

In summary, we have investigated the structural and electronic properties of reconstruction defects in the core of a 30° partial dislocation in silicon and in gallium arsenide. We computed for the first time the formation energies of these antiphase defects. The concentration of APDs in the dislocation cores should be much larger in GaAs than in Si. We found that the formation energy of the antiphase defects scales with the respective reconstruction energy [5]. This suggests that all the energetics, and consequently the concentration of defects in the dislocation cores, should follow some universal scaling law. We additionally computed the Mott–Hubbard potential for an APD in silicon. The positive, and large, value of the potential indicates that the APDs in silicon are electrically active and detectable by EPR.

Kinetic Monte Carlo study of dislocation motion in silicon: soliton model and hydrogen enhanced glide

S. Scarle*, N. Martsinovich, C.P. Ewels, M.I. Heggie

CPES, University of Sussex, Falmer, Brighton, BN1 9QJ, UK

Abstract

The problems with dislocations in semiconductors are becoming tractable with modern computing by hybrid techniques. These apply static first principles calculations of energetics for important processes (e.g. kink formation and migration energies) and kinetic Monte Carlo techniques to follow the dynamic interaction of these processes over length and time scales inaccessible to, for example, molecular dynamic simulation. The simplest model system for covalent and ceramic solids is silicon, but there is debate over the structure and properties of dislocations there. The movement of the dislocation by the simple bond switching mechanism was studied from first principles, finding activation energies close to experiment, but lately the alternative mechanism invoking free radicals or solitons was found to give similar energies. We report results from an *n*-fold way kinetic Monte Carlo approach, applied to a simple system to verify the standard model for kink pair nucleation limited dislocation glide (the Hirth–Lothe model). We then apply an improved technique to the kinetics of the soliton model and to hydrogen enhanced dislocation glide. © 2001 Elsevier Science B.V. All rights reserved.

1. Introduction

The strength of ductile materials is set by dislocation motion on the densest packed crystal glide planes. Dislocation motion comes about from the thermally activated process of generating kink pairs, which with the application of an external stress are forced apart. There is much evidence for the existence of kinks from pulse deformation, internal friction, weak-beam electron microscopy, and spectroscopy.

In this work we shall present two *n*-fold way kinetic Monte Carlo (nkMC) models of dislocation motion dynamics. From the first of which, general results from the model kink behaviour shall be shown and compared to the standard work in the field, Hirth–Lothe theory (HL) [1]. Following this, we shall use an improved description of the dislocation line in the nkMC to look

at soliton and hydrogen–soliton affected dislocation motion, at a 90° partial dislocation in silicon.

2. Description of models

Predictive calculation of mechanical properties is a fundamental problem in materials science. The only viable approach is using the idea of *multi-scale modelling*, where properties and energies of fundamental interactions are calculated using atomic scale techniques. The resulting data then being incorporated into larger scale simulations. We have taken previous density functional theory (DFT) calculations, carried out within the group using the AIMPRO code [2], and applied them to nkMC.

In both our models, dislocation segments are assumed to lie in Peierls minima. The lattice is infinite in the direction of motion and periodic in the direction perpendicular to the motion. The dislocation moves

*Corresponding author. Fax: +44-1273-677196.

E-mail address: s.scarle@sussex.ac.uk (S. Scarle).

under the influence of thermal fluctuations and an optional applied stresses. This is via the processes of double-kink nucleation and lateral kink motion in the basic point-wise model, whilst our more advanced model was run so as to include the motions of solitons and H-solitons, and hydrogen impacts on the dislocation line.

The initial state of the dislocation is taken to be perfectly straight, and it evolves via nkMC [3,4]. At each simulation step, all allowed *events* have a rate calculated for them. These can move the dislocation either with or against the stress, since thermal fluctuations can overcome the additional energy bias caused by the stress. Each event's rate is given by

$$R_i = \omega_0 \exp(-\Delta E_i / k_B T), \quad (1)$$

where i = event number, ΔE_i = energy barrier to event i and ω_0 = attempt frequency. The sum of all the rates is used to determine the time before the next event occurs, and the individual rates serve as probabilities for selecting each event.

Instead of attempting a random event and then accepting/rejecting it based on a criterion (the Metropolis Algorithm) [5]. We choose and execute an event from the entire list. So at each step, an event m is randomly chosen from the total M , such that

$$\frac{\sum_{i=0}^{m-1} R_i}{\sum_{i=1}^M R_i} < \xi_1 < \frac{\sum_{i=0}^m R_i}{\sum_{i=1}^M R_i}, \quad \Delta \tau = -\frac{\ln \xi_2}{\sum_{i=1}^M R_i}, \quad (2)$$

where $\Delta \tau$ = time increment, ξ_i = is a random number in the range 0–1. It is this variable time increment which makes nkMC more efficient than Metropolis when R_i 's differ greatly.

Our basic or point-wise model, is the standard manner of describing a dislocation line for Monte Carlo simulations [3,6,7]. The line is represented with a fixed number of sites. Each site i is characterized by its height H_i , being the distance travelled under the stress. For each site, movements up and down are possible which correspond to formation/annihilation or migration of kinks on the line. ΔE_i for these movements is calculated as follows: $\Delta E_i = 2F_k \pm s$ for backward and forward kink-pair nucleation, $\Delta E_i = -2F_k \pm s$ for backward and forward kink-pair annihilation $\Delta E_i = \pm s$ for backward and forward kink migration. With F_k = kink formation energy, $s = \sigma bhl$ the work done by the applied stress to move a kink, where σ = applied stress, b = Burger's vector, h = height of a kink and l = length of a site.

Our second and more flexible model uses what we call a *line-wise* description. The line is divided into a variable number of sections. Each section j is described by its length L_j sites, height H_j and what defect structure it ends with E_j (i.e. a positive or negative kink, soliton, etc.). Longer dislocation lines can be considered with this description, as nucleation events for entire sections of the line can be dealt with as a single event as opposed to many in point-wise. Also, it is far easier to introduce

further end structures to the simulation, and it is coded so that the properties of all ends required are fed in via a parameter file.

3. Investigation of HL model

It is known that dislocation motion is thermal activated with the following T dependence:

$$v = v_0 \exp\left(-\frac{E_A}{k_B T}\right) \quad (3)$$

and according to HL the activation energy $E_A = F_k + W_m$ = sum of kink formation energy F_k , and migration barrier W_m , for lines long enough to ensure that kink lifetime is limited by kink-kink annihilation (the length-independent regime). Whilst $E_A = 2F_k + W_m$ for lines shorter than the kink mean free path $\lambda \propto \exp(-F_k/k_B T)$ (the length-dependent regime).

Simulations were run using the point-wise model with $F_k = 0.2, 0.5$ and 0.8 , in the T range 400–1200 K with applied stress over $s = 0-0.8$ and $W_m = 0$. The dislocation line had 10,000 sites, but at low T in the length-dependent regime lines with 500–20,000 were considered. These parameters were chosen to test HL not to reproduce experimental data. The obtained results reflect basic theoretical predictions: velocity increases with increasing T , velocity faster at higher stress and small values of F_k , at very high $T > 5000$ K dependence of dislocation velocity is reversed and begins to decrease with T . As at high T thermal fluctuations become more influential than the applied stress and the dislocation motion stops being directed.

The T dependence of the dislocation velocity is of the right form; however, in the length regime $E_A \neq F_k$ as from HL, but $2F_k - 2s$. Whilst in the length-dependent regime it is $4F_k - 3s$; see Fig. 1. In order to find an explanation for these discrepancies kink-pair nucleation rate was obtained within the nkMC, and found to agree with HL:

$$J_N \sim \exp\left(-\frac{2F_k - s}{k_B T}\right). \quad (4)$$

The prefactor showing no F_k or s dependence. However, only kinks which survive can assist in the dislocation motion, so we consider fruitful kink-pair nucleation rate $J_F = J_N - J_A$ which is the difference between the rate of kink-pair nucleation J_N and annihilated J_A .

$$J_F \propto \exp\left(-\frac{4F_k - 3s}{k_B T}\right). \quad (5)$$

Using J_F in HL for dislocation velocity in the length-independent and length-dependent regimes gives the same T dependence of dislocation velocities as the nkMC.

Fig. 1. Graph of E_A = activation energy vs. Points show nkMC calculations: triangles $F_k = 0.2$, boxes $F_k = 0.5$ and diamonds $F_k = 0.8$. Solid symbols for length independent and open ones for length dependent. Solid lines show $2F_k - 2s$ and dashed lines $4F_k - 3s$.

4. Soliton and HEDG results

There are two main atomistic models suggested for kink motion in Si, the Jones model or strained bond model, where kink formation and migration are by successive application of Stone–Wales transforms. AIMPRO calculations have given this an $E_A = 1.9$ eV [8]. The other model depends on solitons. The dislocation core of a 90° partial has a phase due to the left or right direction of its reconstruction bonds. At a phase boundary there exists anti-phase defects, or solitons, giving a dangling bond. In chemical terminology a ‘free radical’. It is highly reactive, so can migrate rapidly along the line nucleating kink pairs. These may occasionally be associated with kinks from time to time, but they have unequal lifetimes. AIMPRO calculations on this model give $E_A = 1.8$ eV. This means that both are in close agreement with other, and in broad agreement with experiment where $E_A = 2.2$ eV [9].

Dislocations in semiconductors can be strongly affected by a hydrogen plasma; core states may be passivated [10] and mobility changed. For Si, H reduces E_A from 2.2 to 1.2 eV, for hydrogen enhanced dislocation glide (HEDG) [9]. Assuming the soliton model, the steady state motion of the dislocation ought to be controlled by the migration and formation of solitons and hydrogenated or H-solitons, for which we use the previously published in-house results [11] produced using AIMPRO, for a soliton and a hydrogenated soliton on a 90° partial dislocation in Si, see Table 1. These results were used to form the simulation parameters for our nkMC. This work also appears to give $E_A \approx 1.2$ eV, as migration barriers for H-solitons

Table 1

Results from previous calculations [11]. Results from 231 atom clusters

Structure	Energy (eV)	
	without H	with H

Along dislocation core	0.15	1.05 ^a
Initiating kink-pair	0.29	1.16
Formation energy compared to soliton		
Soliton: kink-pair	+0.11	−0.19

^aIndicates 186 atoms.

and kink H-soliton complexes ~ 1.1 – 1.2 eV. How the H is supplied to the dislocation is uncertain, since the effect depends on a pre-hydrogenation step (typically 1 h under H plasma between 470°C and 540°C). For our simulation, we shall take a population of H-atoms to be diffusing through the silicon and impacting the dislocation line. This H-flux may be expected to spontaneously nucleate soliton pairs and simultaneously, kink pairs, i.e., a complex of a H-soliton with a reconstructed kink pair will be formed in addition to a non-H-soliton. When two H-solitons meet they annihilate and we assume that the H_2 produced pipe diffuses out of the system.

Taking the kinetic theory result for atomic flux = $n\bar{v}/4$, where n = number density and \bar{v} = average particle velocity. With $\bar{v} = 3D/\lambda$, where λ = mean free path and D = diffusion coefficient = $9.1 \times 10^{-7} \exp(-0.48/k_B T) \text{ m}^2 \text{ s}^{-1}$, for c-Si [12]. Assuming that all H-atoms passing through the surface of a cylinder with radius λ centred on the dislocation line impact it, then the rate of impacts on section j will be $R_j = L_j D \pi n^3 / 2$.

Fig. 2 shows our Arrhenius plot for the nkMC using the line-wise description with a shear stress of 70 MPa to match Yonenaga [9], analysis carried out on this plot gave this relation for dislocation velocity v_{dis}

$$v_{\text{dis}} = 6.8 \times 10^{-20} n^{0.98} \exp\left(-\frac{0.45}{k_B T}\right) \text{ m s}^{-1}, \quad (6)$$

where n = H concentration in cm^{-3} , v_{dis} increases with H-concentration in a basically linear fashion.

However, this $E_A = 0.45$ eV is far too low and seems to relate to our influx of H. We suspect that we are allowing our solitons too much freedom and their mean free path is too high, as we have no soliton H-soliton or soliton H interactions. We probably need to include a soliton capturing an H-atom event, and some form of mixed annihilation move whereby a soliton and a H-soliton annihilate to leave a bond centred H-atom (H_{BC}) in the dislocation core. This second move would require the inclusion of further H_{BC} interactions.

Fig. 2. Arrhenius plot of $\text{Log } v_{\text{dis}}$ versus $1/k_B T$ (eV). Legend gives x where $10^x \text{ cm}^{-3} = \text{H atom concentration}$.

5. Conclusions

Our starting work shows agreement to the standard HL theory once the annihilation rate of the kinks was correctly taken into account.

A new and highly adaptable approach to the Monte Carlo simulation of dislocations has been presented, through which the HEDG behaviour of 90° partial dislocations in Si has been investigated. This was in terms of solitons and H-solitons. This gave a $E_A = 0.45 \text{ eV}$, far too low, leading us to suspect further reactions need to be included.

However, the code used for this work is highly configurable meaning that these events can easily be

included. With the assistance of further AIMPRO calculations we will be able to look at the effect on dislocation motion from other dislocation defect structures, for example impurities and vacancies in the dislocation core.

Do we really need configuration interaction theory to understand the negative vacancy in silicon?

U. Gerstmann, E. Rauls, H. Overhof*, Th. Frauenheim

AG Theoretical Physics, Physics Department, University of Paderborn, D33095 Paderborn, Germany

Abstract

In its negative charge state, the lattice vacancy V^- in silicon experiences a C_{2v} Jahn–Teller distortion. In an LCAO picture, the unpaired electron of b_1 symmetry gives rise to a spin density that is concentrated in a (1 $\bar{1}$ 0) plane with a nodal (1 1 0) plane. Hence, the contact hyperfine (hf) interactions with all ligand nuclei in this plane should be zero. The order of magnitude of the nonzero albeit small contact interactions found experimentally was explained by configuration interaction (CI) theory. This raises the question whether the vacancy can be described without the incorporation of CI theory. We have performed an ab initio calculation using the standard local spin density approximation (LSDA) for the exchange–correlation interaction. We obtain the order of magnitude of the hf interaction with the nuclei in the (1 1 0) plane, if we just impose the C_{2v} symmetry on the unrelaxed V_{Si}^- defect state. When taking into account the properly relaxed ligand coordinates, we obtain quantitative agreement with experimental data. Thus for V_{Si}^- in silicon, correlation effects are important and are treated satisfactorily within the LSDA. © 2001 Elsevier Science B.V. All rights reserved.

PACS: 71.15.Mb; 71.55.Cn; 76.30.Da

Keywords: Configuration interaction; LSDA; Hyperfine interaction; Vacancies

1. Introduction

The first review [1] of the EPR spectra of the vacancy already showed that different charge states give rise to different symmetry-lowering Jahn–Teller distortions. In a simple LCAO picture the D_{2d} distortion of V_{Si}^+ and also the C_{2v} distortion of V_{Si}^- could be successfully explained [1,2].

A calculation of the electronic structure of the vacancy by ab initio methods proved to be a major challenge to theorists. Although the first total energy calculations were quite successful [3], it turned out that the calculation of the lattice relaxation was quite cumbersome (see e.g. Refs. [4–6]): the energy surface turned out to be extremely flat such that the position of

the minimum in the coordination space did depend on such details of the calculation like the supercell size and k-point sampling. It turns out that a supercell of at least 216 atoms is required to obtain the symmetry of the lattice relaxation predicted by the LCAO scheme [1] for the neutral vacancy.

For the vacancy in the paramagnetic V^- charge states extremely detailed experimental information is available from electron paramagnetic resonance (EPR) [1] and in particular from electron nuclear double resonance (ENDOR) experiment [7]. Yet, up to now most published theoretical papers dealt with V^0 and none did include spin polarization. The calculation of the hyperfine (hf) interactions with the ligand nuclei for V^- [8], based on the LDA ignoring spin polarization effects, simulates the magnetization density by the particle density of the unpaired gap state.

Since, this state transforms according to the b_1 irreducible representation of the point group C_{2v} , the

*Corresponding author. Tel.: +49-5251-60-2334; fax: +49-5251-60-3435.

E-mail address: h.overhof@phys.upb.de (H. Overhof).

particle density is concentrated in the $(1\bar{1}0)$ plane with a (110) nodal plane. Therefore, Sugino and Oshiyama [8] find the isotropic hf interaction to be zero by symmetry for all nuclei within this (110) plane. In contrast, experimental ENDOR data [7] exhibit small but nonzero contact hf interactions with several shells of nuclei within the (110) plane. Lannoo [9] has shown that the order of magnitude of these interactions can be accounted for in the LCAO picture if excited states are included in a configuration interaction (CI) scheme. This raises the question whether it is necessary to use CI in order to explain the small contact interactions with nuclei on the (110) plane.

In the local spin density approximation (LSDA), the spin density is represented by that of the Kohn–Sham orbitals. The paramagnetic state of V^- with spin $1/2$ is obtained by the occupation of the gap state which transforms according to b_1 with spin up, leaving the spin-down state of this orbital unoccupied. Since all the other orbitals are either unoccupied, or occupied both for spin-up and spin-down, the magnetization density reflects the b_1 symmetry. In a self-consistent calculation, however, the spin polarization of this b_1 orbital is transferred in part to all other Kohn–Sham orbitals. The resulting magnetization density, although still approximately reflecting the b_1 symmetry, may be nonzero even at the (110) nodal planes. Thus a LSDA treatment could in principle be sufficient to understand the hf interactions of V^- .

We investigate this question in the present paper. We start in the next section calculating the relaxed atomic geometry for the V^- state of the vacancy in a supercell calculation. With the atomic coordinates thus obtained we calculate the hf interactions. We show that while the larger interactions are found for nuclei in the $(1\bar{1}0)$ plane, much smaller interactions are found for nuclei in the (110) plane as observed experimentally. We obtain fair agreement of our calculated hf data with experimental ENDOR data [7]. Hence, there is no need to include CI into the calculation of the electronic state of V^- .

2. Total energy calculation of the relaxed geometry

For the calculation of the atomic geometry of the V^- defect we have used the self-consistent charge density-functional theory based tight-binding scheme (SCC-DFTB) [10]. In this calculation no spin polarization was taken into account. Our calculations were done for sc supercells containing 64, 216, and 512 atoms and for fcc supercells with 128 and 250 atoms, respectively. We relaxed all atoms in a conjugate-gradient calculation. Since the energy contour in the configuration space for V^0 is known to be extremely flat [6,5] we started with different point group symmetries (T_d , D_{2d} , C_{2v} , C_{3v} ,

and D_{3d}), keeping the symmetry constraint fixed during relaxation. We have also performed relaxations without symmetry constraints, obtaining similar results.

For the V^{2+} charge state the relaxation maintains the T_d symmetry corresponding to an energy gain of 1.1 eV. For the positive (neutral) charge states a D_{2d} Jahn–Teller distortion lead to an additional gain of 0.12 eV (0.29 eV).

For the negative charge state of the vacancy the 15% inwards relaxation of the nearest neighbors contributed 1.25 eV, while the D_{2d} and C_{2v} distortions accounted for 0.17 and 0.03 eV, respectively. Thus according to a spinless calculation we obtained for V^- a low-spin 2B_1 many-body ground state of C_{2v} symmetry. Since the alternative high-spin state could as well be the ground state, it is necessary to perform a spin-polarized calculation as well.

This has been done in a Green's function scheme using the relaxed coordinates of the SCC-DFTB calculation. Spin densities have been calculated using the linear muffin-tin orbitals method in the atomic-spheres approximation (LMTO-ASA) [11]. For the exchange-correlation potential we have used the LSDA results of Ceperley and Alder [12] in the Perdew–Zunger parametrization scheme [13], including the (small) spin polarization of the core states.

The energy of the 4A_2 high-spin state of V^- in T_d symmetry is by 0.09 eV larger than that of the 2B_1 state in C_{2v} symmetry. Although this difference of the total energies is quite small, we see that an ab initio calculation including the spin polarization predicts the 2B_1 ground state observed experimentally.

For V^- in silicon, the energy gain obtained by spin pairing with 0.11 eV is remarkably small, smaller by a factor of 3 (5) if compared with the respective value for the V_{Si}^- in SiC (V_C^- in diamond). In all cases the main contribution to the relaxation energy comes from the rather large tetrahedral inwards breathing relaxation (–1.25 eV for V^-), whereas the pairing contributes only –0.2 eV to the relaxation energy.

When relaxing the positions of the four nearest neighbors exclusively, we found the two neighbors (a and d in the notation of [1]) in the $(1\bar{1}0)$ plane to move somewhat closer than neighbors b and c . The same was observed by Sugino and Oshiyama [8] in their 64 atom supercell. However, when relaxing the next nearest neighbors as well, the orthorhombic relaxation is reversed, with an $a-d$ distance that is by 10% larger than the $b-c$ distance.

3. Hyperfine interactions

The hf interactions have been calculated using the LMTO-ASA Green's function scheme. For the vacancy in the singly positive charge state we obtain hf

interactions with the nearest neighbors which amount to $a = -99$ MHz and $b = -14.8$ MHz, values that compare well with the experimental data of 103.5 and 13.9 MHz ([1], the absolute signs have not been determined).

Our primary interest is focused on the negative charge state of the vacancy, because here experimental ENDOR data suggested the necessity of a CI calculation. We find minor changes only for the hf interactions with the nuclei in the $(1\bar{1}0)$ plane denoted by *Mad*, if we compare results obtained with spin polarization with those calculated ignoring spin polarization (as in Ref. [8]). But of course, for the nuclei in the (110) plane (denoted by *Mbc* and by *T*, respectively) the contact hf interactions are zero by symmetry in a calculation without spin polarization (as in Ref. [8]). The results listed in Table 1, obtained including spin polarization, compare hf interactions obtained for unrelaxed lattice positions, however assuming a C_{2v} symmetry of the defect, with those for fully relaxed coordinates, and with experimental ENDOR data [7]. Note that for the experimental contact interactions positive values have been assumed. As is evident from Table 1, the contact interactions for most *Mad* nuclei are negative. Since for ^{29}Si the nuclear gyromagnetic factor is negative, this means that the magnetization density at these nuclei is positive. Fig. 1 shows the spin density and the magnetization densities for V^- in the $(1\bar{1}0)$ and (110) planes, respectively. It is evident that most of the hf interaction with the *Mad* nuclei originates directly from the spin density of the gap state. The interactions with the *Mbc* nuclei are about two orders of magnitude

smaller in modulus than those with the *Mad* nuclei in the $(1\bar{1}0)$ plane. Yet the agreement with experimental data for the latter is comparable to the agreement observed for the former.

It is interesting to compare the magnetization densities in the (110) plane with the particle densities shown in Fig. 1. For the a_1' gap state (occupied both with spin-up and spin-down) the induced magnetization density is negative and closely resembles the (positive) particle density both in the (110) and the $(1\bar{1}0)$ plane, whereas for the a_1' resonance the induced magnetization is positive in both planes. In summary, the total magnetization density in the $(1\bar{1}0)$ plane is positive in rather large regions between the nuclear positions, however, with very small negative values at most of the *Mbc* nuclei. Among the excited configurations with 2B_1 symmetry the term denoted Ψ_4 in Ref. [9], for which the a_1' state is occupied as spin-up and the a_1' is occupied as spin-down, would lead to a magnetization density that matches that of the LSDA calculation for the (110) plane. The present LSDA predicts the magnetization density at the *Mad* nuclei to be negative (with the possible exception of *Mbc5*). Unfortunately, this prediction cannot be checked against experiment because the absolute signs of the experimental contact hf interactions are not known.

5. Conclusions

We have confirmed that the ligand hf interactions with the *Mad* nuclei can be obtained from the spin density of the unpaired gap state. However, the much

^aThe ligand hf interactions calculated for an unrelaxed V^- with a C_{2v} symmetry constraint and for the V^- with the relaxed coordinates from the SCC-DFTB calculation are compared with the experimental ENDOR data of Sprenger et al. [7].

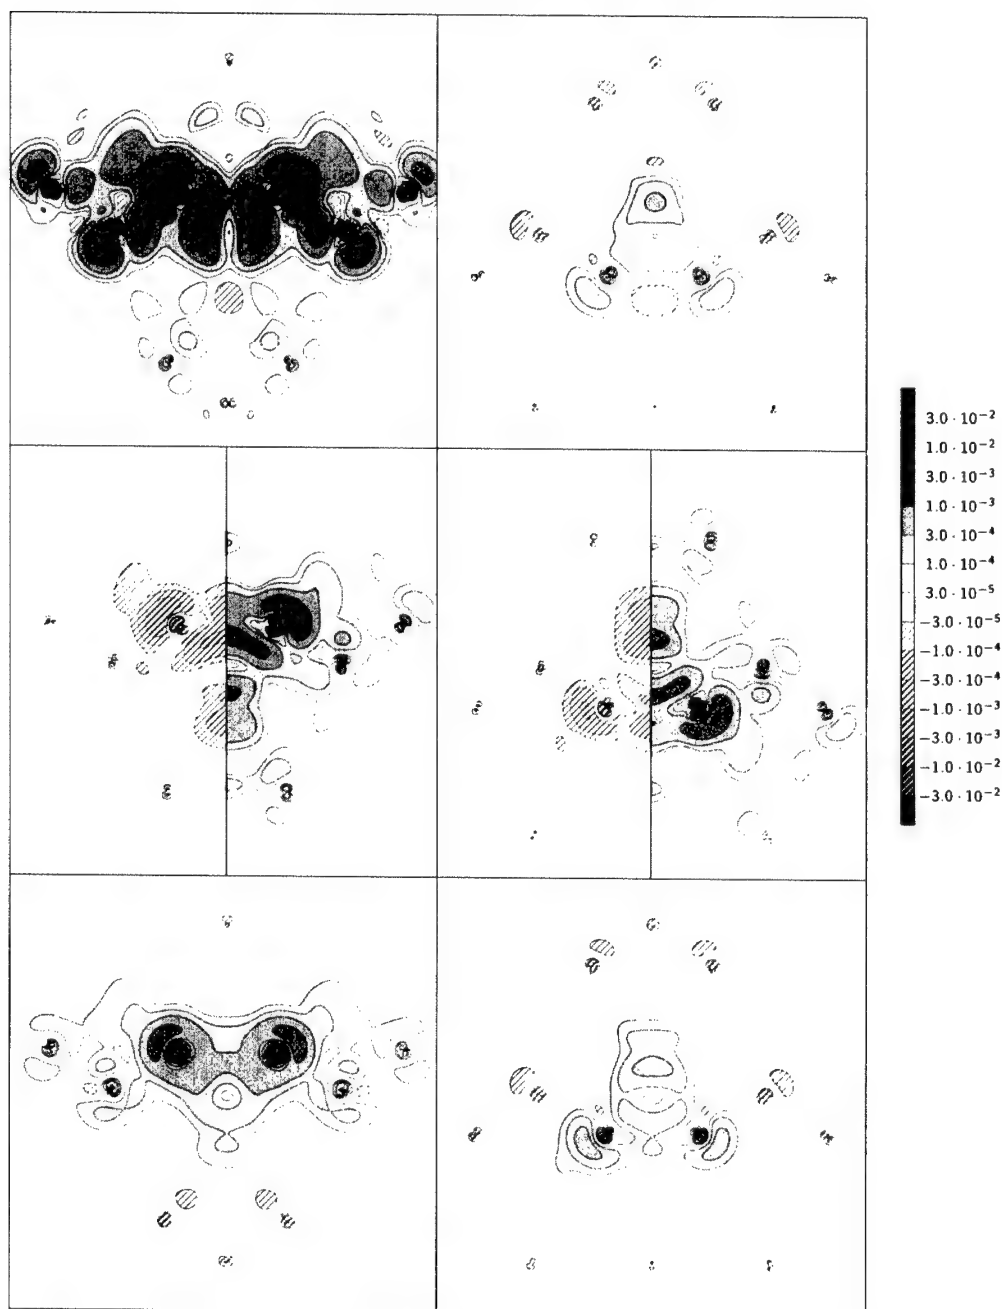

Fig. 1. Contour plots for the V^- vacancy. The top row shows the total magnetization density in the $(1\ 1\ 0)$ (left) and $(1\ 1\ 0)$ planes (right). In the center row the figures are split into magnetization density (left half) and particle density (right half) for the a'' state in the $(1\ 1\ 0)$ (left figure) and $(1\ 1\ 0)$ planes (right figure). In the lower row the magnetization density induced in the valence band is shown in the $(1\ 1\ 0)$ plane (left) and in the $(1\ 1\ 0)$ plane (right).

smaller interactions with the Mbc and T nuclei cannot be obtained without a fair representation of the lattice relaxation and of the spin polarization that is caused by the unpaired spin of the gap state. The fair agreement with experimental data shown in this paper proves that

for V^- spin polarization effects are important and can be satisfactorily treated within the LSDA, without the need to include CI terms. This is quite fortunate, since presently quantitative CI calculation for V^- would be extremely ambitious.

Abstract

Equilibrium concentration of vacancies under the anisotropic stress field around an impurity is investigated. The anisotropy of the work by anisotropic stress is considered. Threshold change of equilibrium concentration of vacancies corresponding to the reported change of void density by B and Sb doping is found. By using this, we can predict the void density change in doped Si. © 2001 Published by Elsevier Science B.V.

Keywords: Equilibrium concentration; Vacancies; Impurities; Stress

1. Introduction

Void defects (vacancy type defects) were found in as-grown Czochralski silicon (CZ) crystal. These cause the degradation of metal-oxide-semiconductor device performance [1]. Therefore, epitaxial wafer, which excludes void defects in device active region, has been used for hi-end devices. High concentration boron (B) doped CZ-Si is used as substrate of epitaxial film. It has been reported that the number of void defects decreases and the location of the oxidation induced stacking fault ring (OSF-ring) moves inward by high concentration B doping in CZ-Si [2]. Recently, there is a tendency that B concentration in epitaxial wafer decreases. This means that decrease of void defects due to B doping is suppressed. To control void defects, it is important to clarify the mechanism of the change of ones due to impurity doping. The change of defects is considered to be due to the change of point defect

concentration. Though various models such as Fermi level effect [3] and size effect [4] are proposed for the origin of point defect concentration change by doping, it is not clear yet.

We have been investigated the effects of stress on the behavior of point defects in a growing crystal [5]. We considered the change of equilibrium concentration of vacancies by the impurity doping is due to stress around impurity. On the basis of experimental data on increase of vacancy concentration due to Sn doping [6], we have successfully analyzed this by performing phenomenological treatment of equilibrium concentration change of vacancies as stress effect [7]. In this paper, we analyze this further by considering the anisotropic stress field around an impurity in detail. In Section 2, basic equations for the equilibrium point defect concentration under isotropic stress and the anisotropic stress field around an impurity are described. In Section 3, we consider the anisotropy of the work under the anisotropic stress field and formulate equilibrium concentration of vacancies in impurity doped Si. In Section 4, we calculate the change of equilibrium concentration of vacancies corresponding to the impurity species and concentration, which changes void density. We show that the change of void defects due to impurity doping is caused by stress by the impurity.

2. Basic equations

2.1. Equilibrium concentration of vacancies under isotropic stress

Previously, Cowern et al. [8] have formulated equilibrium concentration of vacancies under the homogeneous stress field [8]. It is determined by the work by stress, which is the product of stress σ and relaxation volume ΔV_F (<0) and given as

$$C_V^{\text{eq}} = C_0^{\text{eq}} \exp\left(\frac{\sigma \Delta V_F}{kT}\right). \quad (1)$$

Here, C_0^{eq} is equilibrium concentration in stress-free crystal. Equilibrium concentration increases under the compressive stress ($\sigma < 0$), because the work for formation of vacancy is positive ($\sigma \Delta V_F > 0$).

2.2. Anisotropic stress field around an impurity

Stress field around an impurity in Si matrix is not known yet. Rigid sphere insertion model has been used for the stress around an impurity whose size is different from the matrix atoms [9], i.e., silicon atom is removed from the matrix and impurity atom is put into the vacant site. Fig. 1 is the schematic illustration of displacement of silicon atoms around a large impurity. According to rigid sphere insertion model, around the large impurity compressive stress occurs along the radial (r) direction from the impurity and tensile stress does along its normal (θ and ϕ) directions. Displacement of silicon atom, u , is inversely proportional to the square of distance from impurity r and stress σ is inversely proportional to the cubic of one. They are described as follows:

$$u = \frac{c}{r^2}, \quad (2)$$

$$\sigma_{rr} = -4\mu \frac{c}{r^3}, \quad \sigma_{\theta\theta} = \sigma_{\phi\phi} = 2\mu \frac{c}{r^3}, \quad (3)$$

where $c = 4(r_i - r_0)r_0^2$ ($r \geq 2r_0$). Here r_i and r_0 are the atomic radius of impurity and silicon atom, respectively. μ is the shear modulus. It is to be noted that the stress field around impurity is highly anisotropic. Thus, we have to extend the theory by Cowern et al. to the case of anisotropic stress field.

3. Equilibrium concentration of vacancies under the anisotropic stress field around impurity

3.1. Anisotropy of the work under the anisotropic stress field around impurity

Equilibrium concentration of point defects under stress is determined by the work. The values of stress and relaxation volume are necessary to calculate the work. Stress is given in Section 2. Thus, we discuss another important factor, relaxation volume here.

As shown in Fig. 1, total work for formation of vacancies under the stress is sum of each component of the work along to r , θ and ϕ directions at the distance r from the impurity.

$$w_V = \sigma_{rr}\Delta V_r + \sigma_{\theta\theta}\Delta V_\theta + \sigma_{\phi\phi}\Delta V_\phi, \quad (4)$$

where ΔV_r , ΔV_θ and ΔV_ϕ are the relaxation volumes along r , θ and ϕ directions, respectively, as shown in Fig. 1. Fig. 2 is the schematic illustration of the change of relaxation volume under the anisotropic stress field around impurity. Fig. 2(a) shows the configuration of silicon atoms under the homogeneous stress field. Dotted line in Fig. 2(b) is the atomic volume corresponding to each atom in Fig. 2(a). Relaxation volume for formation of vacancies under homogeneous stress field is isotropic as shown by the broken line in Fig. 2(b). So far, there is no consideration of the change of relaxation volume under the anisotropic stress field. Here, we consider that the relaxation volume under the anisotropic stress field ΔV_F is changed anisotropically from that under the isotropic stress to relax anisotropic

Fig. 1. Schematic illustration of displacement of silicon atom and volume change for formation of vacancy around a large impurity.

Fig. 2. Schematic illustration of the change of relaxation volume under the anisotropic stress field around an impurity.

stress. In case of large impurity doping as shown in Fig. 2(a), the inward relaxation around vacancy (displacement of surrounding atomic) is increased along the r direction (compressive), whereas decreased in the θ and ϕ directions (tensile) indicated by solid line in Fig. 2(b).

Next, we calculate w_V . Under the isotropic stress field, because of $\sigma_{rr} + \sigma_{\theta\theta} + \sigma_{\phi\phi} = 0$ as shown in Eq. (3), the sum of work by the homogeneous relaxation is zero. Under the anisotropic stress field, the relaxation volume changes to the hatched anisotropic region in Fig. 2(b). We call these anisotropic components of relaxation volume, Δv . In large impurity doped Si as shown in Fig. 2(b) it is clear that $\Delta v_r < 0$, $\Delta v_\theta > 0$, $\Delta v_\phi > 0$.

Because of $\sigma_{rr}\Delta v_r > 0$ ($\because \sigma_{rr} < 0$), $\sigma_{\theta\theta}\Delta v_\theta > 0$ ($\because \sigma_{\theta\theta} > 0$) and $\sigma_{\phi\phi}\Delta v_\phi > 0$ ($\because \sigma_{\phi\phi} > 0$) in large impurity doped Si, w_V is always positive and equilibrium concentration of vacancy increases. For the quantitative discussion, relaxation volume should be examined in more detail. Relaxation of stress is achieved by the removal of displacement u by impurity. Therefore, it is assumed that Δv has the same dependence on r with u . It is inversely proportional to the square of r and described as

$$\Delta v_{r,\theta,\phi} = \Delta v_{r_0,\theta_0,\phi_0} \frac{(2r_0)^2}{r^2}, \quad (5)$$

where Δv_0 is the relaxation volume for formation of vacancy at nearest-neighbor ($2r_0$) of impurity. Substituting Eqs. (3) and (5) into Eq. (4), w_V is described as a function of r ,

$$\begin{aligned} w_V &= -4\mu c \frac{1}{r^3} \times \Delta v_{r_0} \frac{(2r_0)^3}{r^2} + 2\mu c \frac{1}{r^3} \times \Delta v_{\theta_0} \frac{(2r_0)^3}{r^2} \\ &\quad + 2\mu c \frac{1}{r^3} \times \Delta v_{\phi_0} \frac{(2r_0)^3}{r^2} \\ &= -4\mu c \frac{(2r_0)^2}{r^5} \left(\Delta v_{r_0} - \frac{\Delta v_{\theta_0}}{2} - \frac{\Delta v_{\phi_0}}{2} \right) \\ &= -4\mu c \frac{(2r_0)^2}{r^5} \Delta V_R. \end{aligned} \quad (6)$$

Here $\Delta v_{r_0} - (\Delta v_{\theta_0}/2) - (\Delta v_{\phi_0}/2) = \Delta V_R$.

3.2. Formulation of equilibrium concentration of vacancies under the anisotropic stress by impurity

Using the work obtained in the above section, equilibrium concentration of vacancies under the anisotropic stress field is formulated. For simplicity, homogeneous distribution of impurities with constant distance d is considered. The work averaged from neighboring site of impurity, $2r_0$, to $d/2$ is given as

$$\begin{aligned} W &= \frac{\int_{2r_0}^{d/2} -4\mu c (2r_0)^2 / r^5 \Delta V_R 4\pi r^2 dr}{4\pi/3(d/2)^2 - 4\pi/3(2r_0)^2} \\ &= -48\mu c \Delta V_R \frac{1}{d^3}. \end{aligned} \quad (7)$$

The relationship of $1/d^3 = N$ (N is the concentration of impurity) is held for a homogeneous distribution. Therefore the work is given as a function of N ,

$$W = -48\mu c d^3 V_R N. \quad (8)$$

Using the work shown in Eq. (8), equilibrium concentration is given as

$$\begin{aligned} C_0^{\text{eq}} &= C_0^{\text{eq}} \exp(\sigma \Delta V_F / kT) \\ &= C_0^{\text{eq}} \exp(W / kT) \\ &= C_0^{\text{eq}} \exp(-48\mu c \Delta V_R N / kT) \\ &= C_0^{\text{eq}} \exp\{-192\mu(r_i - r_0)r_0^2 \Delta V_R N / kT\}, \end{aligned} \quad (9)$$

where C_0^{eq} is equilibrium concentration in undoped crystal. So far, the effect of stress due to impurity doping on the change of equilibrium concentration of vacancies is not known. In this paper, thus, it is found that the equilibrium concentration of vacancies has an exponential dependence on the product of $(r_i - r_0)$ and N . This is interpreted as follows; work per impurity is determined by the stress, i.e. difference of atomic radius between silicon and impurity. Also the work per unit volume is proportional to the number of impurity N .

4. Analysis of void density change by the stress due to impurity doping

Now, we calculate the equilibrium concentration of vacancies and discuss its role in the reported change of void densities by impurity doping. Recently, Ono et al. [10] reported that Sb doping increases COP (void) density in addition to the well known decrease of one by B doping [10]. In their report, B doping for $6 \times 10^{18}/\text{cm}^3$ and $1.5 \times 10^{19}/\text{cm}^3$ decreases void density, whereas Sb doping for $5 \times 10^{18}/\text{cm}^3$ increases one. On the other hand, B doping for $1 \times 10^{15}/\text{cm}^3$ does not change void density and the number of void defects in $1 \times 10^{18}/\text{cm}^3$ Sb doped Si is the same as that. Therefore, we consider that Sb doping for $1 \times 10^{18}/\text{cm}^3$ does not affect the void density.

The changes of equilibrium concentration of vacancies corresponding to impurity concentration corresponding to void density changes are calculated. Only unknown parameter for calculation is ΔV_R . It is assumed to be -6.67 \AA^3 ($\frac{1}{3}$ of atomic volume of silicon). Fig. 3 shows calculated results. Decreases of vacancy concentration by B doping for $1 \times 10^{15}/\text{cm}^3$, $6 \times 10^{18}/\text{cm}^3$ and $1.5 \times 10^{19}/\text{cm}^3$ are 0.0002% (cross mark), 0.96% (closed circle) and 2.39% (closed circle), respectively. On the other hand, increase of one by Sb doping for $1 \times 10^{18}/\text{cm}^3$ and $5 \times 10^{18}/\text{cm}^3$ are 0.011% (cross mark) and 0.53% (open circle), respectively. Though these values change by changing ΔV_R , relative amount keeps the same tendency. It is to be noted that the threshold changes of equilibrium concentration of vacancies required for void density change are nearly equal in the two cases (dotted lines in Fig. 3), irrespective of the dopant type, atomic size difference and impurity concentration. This supports that the change of void density is caused by the stress effect. As the threshold vacancy concentration corresponding to

void density change is found, we can predict void density change in any impurity doped Si.

5. Summary

We examine the stress effect due to impurity doping on the change of equilibrium concentration of vacancy. Considering the anisotropy of the work by the anisotropic stress due to impurity, equilibrium concentration of vacancies is formulated. The changes of equilibrium concentration of vacancies are calculated in B and Sb doped Si where void density change is reported. Threshold value corresponding to void density change is found, irrespective of the dopant type, atomic size difference and impurity concentration. This makes it possible to predict void density change in impurity doped Si.

Mechanisms of capture- and recombination-enhanced defect reactions in semiconductors

Yuzo Shinozuka*

Faculty of Systems Engineering, Wakayama University, Skaedani 930, Wakayama, 640-8510, Japan

Abstract

Proposed mechanisms on defect reactions in semiconductors (defect creation, annihilation, multiplication, reconstruction, impurity diffusion, etc.) are reexamined with particular attention to the instability of the lattice and the transient lattice vibration induced by successive carrier captures. (1) Thermal activation process to overcome the potential barrier U_n : it depends on the electronic state n and the reaction rate is given by $p_0 \exp(-U_n/k_B T)$. (2) Instability mechanism: the lattice relaxation after an electronic transition at a defect promptly induces the reaction coordinate Q_R . (3) Phonon kick mechanism (single capture): if the relaxation mode Q_1 partially includes Q_R , an electronic transition to the state n enhances the defect reaction during the lattice relaxation time $\tau \sim 2\pi/\Delta\omega$ where $\Delta\omega$ is the width of the frequency distribution of related phonons. (4) Phonon kick mechanism (recombination): if N pairs of electron and hole are captured within a short period $\tau \sim 2\pi/\Delta\omega$ and the central frequency ω_R of Q_R is not so different from ω_0 of Q_1 , the band gap energy E_g is transformed by a series of coherent carrier captures into the lattice vibration energy. The defect reaction rate is given by $(\omega_0/2\pi)\exp(-E_i^{\text{act}}/k_B T)$ because only the first capture ($i = e, h$) is to be activated. On the other hand, if ω_R is much different from ω_0 , the rate is $(\omega_0/2\pi)\exp(-U_0^*/k_B T)$ with $U_0 = (E_i^{\text{act}} + E_i^{\text{th}})$ because the N phonon-kicks are out of phase. © 2001 Elsevier Science B.V. Keywords: Defect reaction; Instability; Phonon kick; Coherent capture

1. Introduction

Electronic transitions sometimes induce or enhance defect reactions in semiconductors, such as impurity diffusion, structural change of a defect (creation, annihilation and multiplication), and climb and glide motions of dislocation [1]. Several models have been proposed so far to explain mechanisms, which can be classified into two categories as schematically shown in Fig. 1 [2]. One is the structural instability mechanism (Fig. 1(a)) where an electronic excitation to a particular state of the defect induces a symmetry breaking atomic motion such as the off-center displacement. The other mechanism is the recombination enhanced (phonon kick) mechanism (Fig. 1(b))

[3–5], where the transient lattice vibration induced by carrier capture(s) enhances the defect reaction. In order to control defect reactions in semiconductors, detailed understanding of the mechanisms and their relations are necessary. The purpose of the present paper is to review the proposed mechanisms and classify them with particular attention to the lattice instability and the dynamics of the lattice relaxation after electronic excitations.

2. Instability

2.1. Thermal process

The stable lattice structure of a condensed material is different for different electronic states. Then electronic transitions (excitation, deexcitation, carrier capture, etc) affect the atomic movements around defects, sometimes

Fig. 1. Two categories of mechanisms for defect reactions enhanced by electronic excitations.

inducing defect reactions. Usually defect reactions are induced by a thermal activation of phonons to overcome the potential barrier U_n , which depends on the electronic state n . The reaction rate p is given by $p_0 \exp(-U_n/k_B T)$, with a prefactor $p_0 \sim 2\pi/\omega_0$, where ω_0 is the mean phonon frequency. In Fig. 1(a) an electronic excitation to ex_1 decreases the potential barrier height (from U to U_1) of the reaction. Then we can expect the Fermi energy dependence of the reaction rate. The reaction rate is increased as $p_0 \exp(-U_n/k_B T)$ during the life time τ of the excited state. Thus the enhancement of the reaction can be observed only in the case of $p\tau > 1$.

2.2. Instability

In Fig. 1(a) an excitation to ex_2 state promptly generates the instability of the lattice. If the lattice relaxation mode is symmetric such as A_{1g} mode, it unlikely generates the reaction. Thus the off-center distortion plays an important role in (the precursor stage of) the defect reaction.

Many substitutional impurities in tetrahedrally bonded covalent semiconductors have been found to show the off-center instability to C_{3v} , such as DX-center in AlGaAs, EL2 in GaAs and N in Si. It can be understood with the Jahn–Teller effect [6], which states that if the electronic state is degenerate the atomic structure automatically lowers the symmetry to reduce the degeneracy. In order to discuss the off-center instability of an impurity in semiconductors, the key point is whether the J–T displacements contain the displacement R_0 of the impurity atom located at the center [7]. It has been shown that an impurity atom at any position with the inversion symmetry, such as O_h does not show the instability caused by the J–T effect. This is because the irreducible representations for any system with the inversion symmetry are classified into gerade and ungerade. All the J–T distortion modes are gerade while the displacement of the central atom always belongs to ungerade modes. On the other hand, those positions without the inversion symmetry show the off-center instability for degenerate electronic states. For example, in T_d case, triply degenerate T_1 and T_2 states induce T_2 -type mode resulting in the off-center

instability. El-Maghraby and Shinozuka [8] have comprehensively studied the structural instability in the T_d symmetry system including the effect of spin and the electron–electron interaction. One of the most striking results is that due to the absence in electron–hole symmetry in the sp^3 bonded system, deep neutral acceptors A^0 always show the off-center instability. This presents a possibility of AX-center, which may explain the low efficiency of p-type doping in some semiconductors.

2.3. Impurity diffusion

Let us next discuss the impurity diffusion by the interstitial mechanism, where an impurity atom diffuses via interstitial positions. An interstitial impurity may occupy a larger vacant site in the host lattice, then they have high point symmetry and we can then apply the above result. If a localized electronic state which shows the off-center J–T instability at a position A continuously changes into a state which does not show at a position B and vice versa, the diffusion is enhanced by the electronic excitation and deexcitation. The self-interstitial in Si is shown to be of this type [9]. This mechanism is similar to the Bourgoin–Corbett mechanism [10,11], where the electronic transition is a carrier capture process.

3. Recombination enhanced defect reaction

3.1. Configuration diagram for deep-level defect

Some deep-level defects whose electronic state strongly couples with the lattice act as a nonradiative multiphonon recombination center [12,13]. Fig. 2 shows a typical example of the configuration coordinate

Fig. 2. The configuration coordinate diagram for non-radiative multiphonon recombination process at deep-level defects.

diagram of a deep-level defect. Since there are many carriers in real situation, the system cannot be treated as the ground state + a few excited states. In Fig. 2 [n_c free e + n_h free h] indicates that there are n_c free electrons and n_h free holes with neutral defect (D^0) in order to discuss the correlation between successive captures. Let q_k denote the k th normal mode of the lattice vibration coupled with a localized electronic state with an angular frequency ω_k . The suffix k stands for the wave numbers and the modes. Without loss of generality we assume that the equilibrium positions of lattice modes are $\{q_k = 0\}$ when the defect is neutral (D^0) and $\{q_k = \bar{q}_k\}$ when the defect is occupied by an electron (D^-). It is convenient to introduce the interaction mode $Q_1 = (1/\bar{Q}_1) \sum_k \omega_k^2 \bar{q}_k q_k$ where \bar{Q}_1 denotes its equilibrium position for D^- . The net effect of lattice distortions $\{q_k\}$ to the electron-hole system appears only through Q_1 in the adiabatic approximation. The lattice relaxation energy is given by $E_{LR} = \sum_k \omega_k^2 \bar{q}_k^2 / 2 \equiv \bar{Q}_1^2 / 2$. After an electron (hole) capture which needs an activation energy, $E_c^{\text{act}}(E_h^{\text{act}})$, transient lattice vibrations are induced, where $q_k \propto \cos \omega_k t$. The motion of Q_1 shows damping oscillation because it consists of many normal modes with different frequencies. During the relaxation an electronic energy equal to the thermal depth $E_c^{\text{th}}(E_h^{\text{th}} = E_g - E_c^{\text{th}})$ of an electron (hole) is converted to phonon energies. As a result of an e-h pair recombination, the electronic energy, $E_g = E_c^{\text{th}} + E_h^{\text{th}}$, is converted to the lattice vibration energy.

3.2. Enhanced reaction by single capture

When the defect is partially isolated and can be considered as a defect molecule, a carrier capture supplies the thermal energy ($\sim E_c^{\text{th}}$ or E_h^{th}) to the molecule. Then the reaction rate will be increased as $p \exp(-U_0^*/k_B T)$ with $U_0^* \sim U_0 - E_c^{\text{th}}$ (or E_h^{th}). This is the Week-Tully-Kimerling mechanism [3]. Another mechanism has been proposed by Sumi [4,5], who discussed the time evolution of the transient lattice vibration after a capture, neglecting the damping. He showed that the activation energy U_0 for a defect reaction is reduced to $U_0 - (E_i^{\text{act}} + E_i^{\text{th}})$

or

$$\left(\sqrt{U_0} - |\cos \theta| \sqrt{E_i^{\text{act}} + E_i^{\text{th}}} \right)^2 / (1 - \cos^2 \theta),$$

where $i = e$ or h , and θ is the angle between Q_1 and Q_R .

3.3. Correlation between successive captures

It has been suggested that the transient vibration induced by a carrier capture enhances the probability of a following capture of the opposite carrier [2,4,5,12,13].

Recently Shinozuka and Karatsu have simulated the transient lattice vibration induced by successive captures and its effect on the subsequent capture process [14–16]. If N pairs of electrons and holes are sequentially captured by the defect, each occurred at $t_{c1} < t_{h1} < t_{c2} < t_{h2} < \dots < t_{cN} < t_{hN}$, the time evolution of $Q_1(t)$ for $t_{hN} < t$ is given by

$$Q_1(t) = Q_1^{\text{before}}(t) + \bar{Q}_1 \left\{ - \sum_j^N \exp[-\Delta\omega^2(t - t_{cj})^2/4] \cos \omega_0(t - t_{cj}) + \sum_j^N \exp[-\Delta\omega^2(t - t_{hj})^2/4] \cos \omega_0(t - t_{hj}) \right\}, \quad (1)$$

for a system whose phonon frequency ω_k distribution is given by a Gaussian with the central frequency ω_0 and the width $\Delta\omega$. Here $Q_1^{\text{before}}(t)$ is the time dependence if the captures of N electron-hole pairs were absent. Thus, $Q_1(t)$ is shown to be a linear combination of damping oscillations, each starts at time t_{cj} or t_{hj} and lasts for the same duration $\tau \sim 2\pi/\Delta\omega$. It should be called here that the nonradiative capture time t_{cj} and t_{hj} cannot take an arbitrary value but should be obeyed by a probability process: the capture takes place only when $Q_1(t)$ crosses a critical point Q_c or Q_h , the intersection of two adiabatic potentials (Fig. 2).

3.4. Reaction enhanced by successive captures

Finally we discuss the effect of the transient vibration Eq. (1) on defect reactions. We will use the following assumptions:

- The first electron capture takes place by a thermal activation Q_1 to Q_c with the activation energy E_c^{act} .
- If $Q_1(t)$ crosses at the point $Q_c(Q_h)$ of the adiabatic potentials, there is a probability $p_c(p_h)$ per time to capture an electron (hole) nonradiatively. $p_c(p_h) \sim \omega_0/2\pi$ in the adiabatic limit [4,5].
- The motion of the reaction coordinate is given by $Q_R(t) = \sum_k f_k q_k(t)$, whose frequency distribution is given by a Gaussian with the central frequency ω_R and the width $\Delta\omega$.
- If $Q_R(t)$ overcomes the critical point Q_c , the defect reaction takes place.

Fig. 3 shows a typical example of the time evolutions of the interaction mode $Q_1(t)$ and the reaction mode $Q_R(t)$. The values of parameters used are indicated in the figure. As can be seen, every capture process enhances the vibration of $Q_1(t)$. On the other hand, it is not so for $Q_R(t)$ in $\omega_0 \neq \omega_R$ case, because the timing of push and pull for $Q_R(t)$ is out of phase.

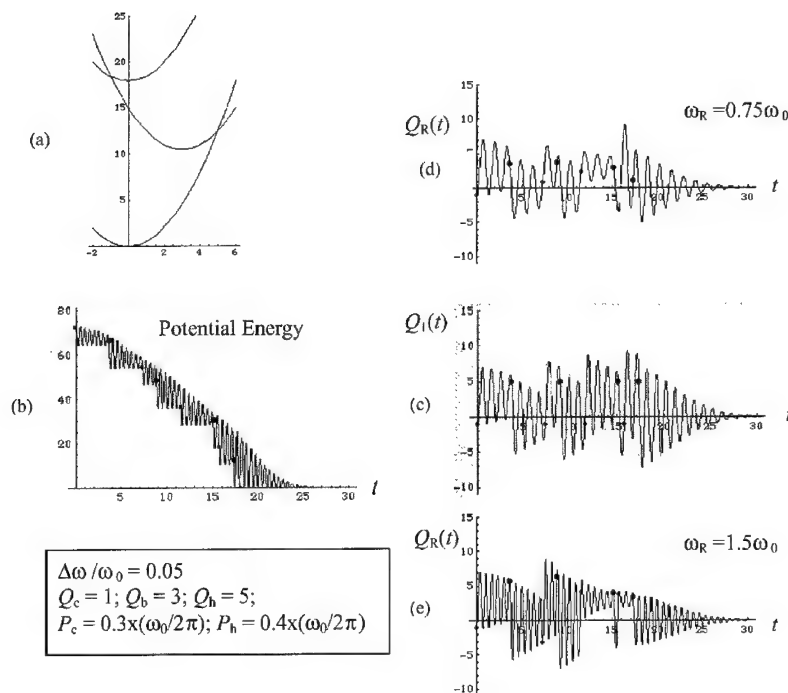

Fig. 3. The transient lattice vibrations induced by successive carrier captures for the interaction mode $Q_I(t)$ and the reaction coordinate $Q_R(t)$. Large (small) black circle in (b)–(e) indicates the capture time $t_{ej}(t_{hj})$ of an electron (hole).

4. Summary

Proposed mechanisms on defect reactions in semiconductors are reexamined with particular attention to the instability of the lattice and the transient lattice vibration induced by successive carrier captures. The possibility of defect reaction has been discussed in connection with the instability of the lattice and the transient induced lattice vibration. In the latter case, the condition for the coherent captures turns out to be $p_e \tau \sim p_h \tau \sim \omega_0 / \Delta\omega > 1$. Then if N pairs of electrons and holes are captured within a short period $\sim 2\pi / \Delta\omega$, the amplitude of the interaction mode $Q_I(t)$ increases remarkably. If the central frequency ω_R of the reaction coordinate Q_R is not so different from ω_0 of the interaction mode Q_I , the band gap energy $E_g = E_e^{\text{th}} + E_h^{\text{th}}$ can be transformed by a series of coherent carrier captures into the lattice vibration energy. The defect reaction rate is given by $(\omega_0/2\pi)\exp(-E_i^{\text{act}}/k_B T)$ because only the first capture ($i = e, h$) is to be activated. On the other hand, if ω_R is much different from ω_0 , the rate is $(\omega_0/2\pi)\exp(-U_0^*/k_B T)$ with $U_0 = (E_i^{\text{act}} + E_i^{\text{th}})$ because the N phonon-kicks are out of phase.

Dynamics of Si self-interstitial clustering using the fast-diffusing I_3 cluster

M. Gharaibeh^a, S.K. Estreicher^{a,*}, P.A. Fedders^b

Abstract

Recent ab initio molecular-dynamics simulations have shown that the di-interstitial (I_2) and the stable tri-interstitial (I_3^a) clusters in Si are highly mobile. In these complexes, the two (or three) self-interstitials share a single bond-centered site, a feature which greatly facilitates exchange processes and is responsible for the rapid diffusion. In this contribution, we consider the possibility that the precipitation of self-interstitials results from the clustering of I_3 'units' rather than isolated Is. We study the interactions $I_3 + I_3 \rightarrow I_6$ and $I_6 + I_3 \rightarrow I_9$ by bringing an I_3 toward either another I_3 or I_6 along various crystalline directions in 216 host atoms supercells. The calculations show that these reactions occur at a substantial gain in energy and that the stacking along some directions is energetically preferred over others. The $I_6 + I_2 \rightarrow I_8$ reaction leads to a very stable cluster. The results suggest that precipitation mechanisms involving rapidly moving self-interstitial clusters could play an important role in the formation of extended defects. © 2001 Elsevier Science B.V. Keywords: Molecular dynamics; Self-interstitials; Silicon

1. Introduction

Large concentrations of self-interstitials (Is) in Si are generated during common processing steps, such as ion implantation. The self-interstitials rapidly form large precipitates, in particular $\{311\}$ platelets, which play critical role(s) in the transient-enhanced diffusion of the shallow B acceptor; recent reviews are in Ref. [1]. A number of theorists have been involved in the calculation of the structures and electronic properties of small I_n clusters [2–12] as well as precipitation mechanisms [13,14]. The clustering or precipitation is always assumed to result from interactions involving isolated and fast-diffusing Is. However, the energies gained in the reaction $I_{n-1} + I \rightarrow I_n$ are often found to be roughly constant for many values of n , with larger energy gains for specific small clusters such as I_3, I_4 or I_8 . No

conclusive precipitation mechanism has yet emerged from calculations.

Recent ab initio molecular-dynamics (MD) simulations [15] have shown that the I_2 cluster as well as the most stable configuration of the I_3 complex (originally labeled I_3^a) diffuse remarkably fast even at low temperatures. Both of these clusters are centered around a single bond-centered (BC) site and this feature facilitates the exchange processes involved in the diffusion. In this paper, we examine the possibility that the highly mobile I_3 is the building block of larger defect structures by studying the reactions $I_3 + I_3 \rightarrow I_6$ and $I_6 + I_3 \rightarrow I_9$.

2. Methodology

Our MD simulations are done using the SIESTA code [16,17] as described in Ref. [15]. In a nutshell, these are classical MD simulations in which the electronic problem solved at the ab initio level within density-functional theory. The electronic basis sets consist of numerical linear combinations of atomic orbitals. The

Fig. 1. The 216-atoms cell (or I_6) is around a centrally located BC site and the second I_3 is placed at other BC sites along various crystalline directions. The directions which lead to large energy gains as the two complexes get closer to each other are labeled: (a) $\langle 0 \bar{1} 1 \rangle$, (b) $\langle 0 \bar{1} \bar{1} \rangle$ and (c) $\langle 2 \bar{1} 1 \rangle$.

crystal is represented by a periodic supercell of 216 host atoms and the k -point sampling is reduced to the Γ point. The basis set on those Si atoms that are at essentially undisturbed crystalline sites is single zeta, but a double-zeta polarized set is used on all the atoms that are away from perfect sites. For example, in the case of I_3 , only the three Is and their two Si nearest-neighbors have the larger basis set. Since the calculations scale as N^3 , where N is the total number of orbitals in the cell, this compromise allows systematic calculations to be performed.

Fig. 1 shows the 216-atoms cell. We place I_3 (or I_6) around a centrally located BC site then place another I_3 at BC sites along various crystalline directions. All the BC sites shown by dots on the figure are considered. For every I_3+I_3 or I_6+I_3 combination, all the structures are quenched and their energies recorded. These complexes are very similar to the isolated I_3 and I_3 or I_6 when at large distances, but they interact and form new complexes when closer to each other.

3. Results

The calculated gains in energy as I_3 approaches another I_3 as a function of their separation and for various approach directions are shown in Fig. 2. The distance between the two complexes is defined as the separation between their respective geometrical centers. In the nearest possible separation, the I_6 complex has formed. Only the easiest approach directions are shown. Note that the largest separation between the two complexes in this cell is slightly over 10 Å, a separation

Fig. 2. Energy gained as the two I_3 complexes get closer to each other to form I_6 . One I_3 is at the origin, the second approaches from the right along the directions shown in Fig. 1.

Fig. 3. The most stable configuration of the I_6 clusters consists of two identical triangles rotated by 60° relative to each other, centered at BC site (dot). The side and top views are shown.

at which some interaction already occurs. We estimate that the reaction $I_3+I_3 \rightarrow I_6$ releases at least 2.5 eV, which is a substantial gain.

We found more than a dozen possible configurations of I_6 . The most stable one is shown in Fig. 3. It is best described as two identical triangles in $\{111\}$ planes, separated by 2.0 Å and centered at a BC site. The triangles are not exactly equilateral (the sides are 2.51, 2.69, and 2.87 Å, respectively) but the entire complex is close to trigonal. It is remarkable that the most stable I_3 and I_6 complexes are both centered at a single BC site. In these two defects, only two host atoms need to be substantially displaced from the equilibrium sites (about 1.6 Å in the case of I_6) in order to accommodate the entire complex.

The calculated gain in energy as I_3 approaches I_6 as a function of their separation and for various approach

Fig. 4. Energy gained as I_3 gets closer to I_6 to form I_9 . The I_6 complex is at the origin and I_3 approaches from the right along the directions shown in Fig. 1.

directions is shown in Fig. 4. The distance between the two complexes is defined as the separation between their respective geometrical centers. In the nearest possible separation, the I_9 complex has formed. Only the easiest approach directions are shown. The reaction $I_6 + I_3 \rightarrow I_9$ releases about 3.0 eV, a gain even larger than that for $I_3 + I_3 \rightarrow I_6$.

We have not yet studied all the possible configuration of I_9 . But the most likely structure can be described as distorted I_6 and I_3 complexes at the second-nearest BC sites. Note that if an even more stable structure of I_9 emerges, the gain in energy that occurs during the clustering will be even larger than 3 eV mentioned above.

The I_8 cluster has been mentioned [12] as a likely precursor of I_n platelets and/or a particularly stable complex. For this reason, we have also considered the reaction $I_6 + I_2 \rightarrow I_8$, which could easily occur since I_2 is highly mobile as well [15]. Preliminary calculations give an energy gain of at least 3.2 eV, confirming that this cluster is particularly stable.

4. Discussion

The issue of self-interstitial precipitation is a challenge for ab initio theory. If one begins with a locally large concentration of Is, they will quickly form small clusters I_n , with $n = 2, 3, 4$, etc. but if I is the only fast-diffusing species, the process is likely to stop there unless a continuous supply of Is is provided. However, theory predicts that the I_2 and one I_3 clusters (as well as one configuration of I_4 [18]) are extremely mobile even at low temperatures. This opens the possibility that the precipitation of Is involves contributions from small clusters such as I_2 or I_3 attracting each other and forming larger precipitates. We have now shown that the

reactions $I_3 + I_3 \rightarrow I_6$ and $I_6 + I_3 \rightarrow I_9$ result in large energy gains of over 2.5 and 3.0 eV, respectively, strongly suggesting that the formation of large precipitates could well involve such clusters.

Abstract

The generation and annihilation of defects upon electron irradiation and subsequent annealing has been studied by high-resolution deep level transient spectroscopy (Laplace DLTS) in phosphorus-doped silicon crystals which were grown by the vacuum float zone technique. It was found that the disappearance of phosphorus–vacancy pairs in the temperature range of 125–175°C is accompanied by a significant reduction in the concentration of C_i-C_s complexes and formation of a defect with an acceptor level at $E_c - 0.21$ eV. The level was assigned to a pair of substitutional carbon atoms (C_s-C_s), which is formed when the free vacancy released upon E-centre annealing is captured by the C_i-C_s complex. © 2001 Elsevier Science B.V. 1. Introduction

The E-centre (phosphorus–vacancy pair) is one of the dominant defects induced by electron irradiation in phosphorus-doped oxygen-lean float-zone-grown (FZ) Si crystals [1]. The defect introduces an acceptor level at about $E_c - 0.45$ eV into the gap [1,2]. Detailed information about electronic properties and structure of this defect in its neutral charge state was obtained by Watkins and Corbett from electron spin resonance data and electron–nuclear double resonance measurements [1].

The E-centre was found to anneal out at about 150°C with annealing well described by first order kinetics [3–6]. This suggests that the dissociation of the complex occurs or it diffuses to a trap species with a high

concentration. However, in spite of a large number of papers related to investigations of the E-centre annihilation process, the annealing mechanism(s) of the complex is uncertain. From the results on the recovery of stress-induced alignment, an activation energy of the defect re-orientation was found to be 0.93 ± 0.05 eV [1]. This value was considered to be the activation energy for the diffusion of the neutral phosphorus–vacancy pair in the lattice. Practically the same value of activation energy has been obtained from studies of the E-centre annealing process [3–6],¹ and the conclusion drawn that the annealing process is related to the migration of the E-centre through the lattice as an entity to some species of trap. The origin of these traps, however, has not been identified unambiguously, and products of the interaction have not been detected. On

¹It was found in Refs. [5,6] that the annealing process of the E-centre is charge-state dependent, being faster in the neutral state ($\Delta E \approx 0.95$ eV) and slower in the negative charge state ($\Delta E \approx 1.25$ eV).

the other hand, there are some indications that the dissociation of the E-centres with the release of free vacancies could occur upon annealing at about 150°C. Supporting evidence for this hypothesis is an increase in A-centre (oxygen–vacancy pair [7,8]) concentration upon disappearance of E-centres [1,9].

2. Experimental

In the present study we have applied the Laplace DLTS technique [10] in combination with low-temperature photoluminescence measurements to study defect reactions associated with the disappearance of the phosphorus–vacancy pair in silicon. Two types of phosphorus-doped Si crystals were used with initial resistivities of 1 and 60 Ωcm. The crystals were grown by the vacuum float zone technique that results in low oxygen content.² Oxygen was not detectable in the crystals by optical absorption measurements at room temperature and so has a concentration of $<10^{15} \text{ cm}^{-3}$, the concentration of substitutional carbon atoms was found to be about $5 \times 10^{15} \text{ cm}^{-3}$. The samples were irradiated with 6 MeV electrons at room temperature. 30 min isochronal annealing was carried out in a nitrogen ambient in the range of 75–350°C with temperature increments of 25°C or 50°C. Changes in defect concentrations upon isothermal annealing at 175°C were also investigated. Gold Schottky diodes were used for the DLTS and LDLS measurements.

3. Experimental results and discussion

Fig. 1 shows conventional DLTS spectra for electron-irradiated samples with initial resistivity of 60 Ωcm just after irradiation and at different stages of isochronal annealing. Several deep levels were introduced into the samples by the irradiation. From the analysis of electron emission and capture processes from/into the traps by means of the Laplace DLTS technique, the values of activation energies for emission and capture cross sections were determined. The results are summarised in Table 1, where the information about the origin of the traps is given as well. This information is based on the comparison of the obtained trap parameters with those known from the literature on radiation-induced traps in FZ-Si crystals [2,11]. The dominant traps induced by irradiation were found to be the interstitial–substitutional carbon pair (C_i-C_s) and the vacancy–phosphorus

Fig. 1. DLTS spectra of FZ-Si samples with initial resistivity of 60 Ωcm after (1) electron irradiation with a fluence of $3 \times 10^{13} \text{ cm}^{-2}$ and subsequent annealing at (2) 200°C and (3) 350°C for 30 min. Inset shows Laplace DLTS spectra at 130 K for Fz-Si samples conventional DLTS spectra of which are shown in Fig. 1.

complex, concentrations of divacancies and A centers were about 25% and less than 5%, respectively, of that of the P–V centre.³

In photoluminescence (PL) spectra of irradiated samples a dominant PL line at 969.5 meV with its characteristic phonon-assisted sideband (“G” line [12]) was observed. This line is known to be related to the C_i-C_s complex [12].

Annealing of the samples in the temperature range 125–175°C resulted in a significant decrease in the magnitude of the DLTS peak at 229 K (E_{229}). It is believed that this process is related to the elimination of E-centres upon annealing. The peak with maximum at about 232 K (E_{232}) remaining after annealing at 200°C (spectrum 2 in Fig. 1) is related to the electron emission from the singly negatively charged state of divacancy. An examination of the spectra shows also significant changes in the magnitudes of peaks with maxima at about 92 K and 134 K (E_{92} and E_{134} , respectively), the former being decreased and the later being increased upon annealing. Application of the Laplace DLTS technique shows that the increase in the magnitude of the peak in the range of 120–150 K is related to the appearance of another electron trap (E_{140}) with emission rates close to those for the electron emission from the doubly negatively charged state of divacancy (E_{134}). The insert in Fig. 1 shows the Laplace DLTS spectra

²Our estimations, which are based on the comparison of introduction rates of V–O and V–P complexes in the crystals with carefully determined phosphorus concentration, give [O] values lower than 10^{14} cm^{-3} in some crystals.

³We used a method of variable filling pulse lengths, which was proposed in Ref. [11], to determine concentrations of A-centres and C_i-C_s complexes.

Table 1
Parameters of deep level traps, which were observed in electron-irradiated FZ-Si crystals

Trap label	Activation energy for electron emission (eV)	Capture cross-section (cm ²)	Identification
E_{92}	0.161	2.4×10^{-15a}	$C_i-C_s(-/0)$
E_{134}	0.240	$5.5 \times 10^{-16} \times \exp(-0.017 \text{ eV/kT})$	$V_2(=/-)$
E_{140}	0.228	$1.8 \times 10^{-16} \times \exp(-0.018 \text{ eV/kT})$	$C_s-C_s(-/0)$
E_{229}	0.453	3.5×10^{-15}	$V-P(-/0)$
E_{232}	0.428	2.2×10^{-15}	$V_2(-/0)$

^a Determined from the data on emission rates (other data are measured directly).

at 130 K for the samples, conventional DLTS spectra of which are shown in Fig. 1. Just after irradiation a peak related to the electron emission from the $V_2(2-)$ state dominates in the spectrum, while after annealing at 200°C two peaks with comparable concentrations are seen. Further annealing at 350°C resulted in disappearance of the $V_2(2-/-)$ -related peak, leaving only a peak which appears after annealing at 125–175°C.

Activation energies for electron emission from the E_{134} and E_{140} traps are given in Table 1. Expressions describing the capture cross sections are also given in Table 1. Our results on the emission and capture characteristics for the E_{134} are consistent with those reported in literature for the $V_2(2-/-)$ level [2]. On the basis of combined analysis of the emission and capture processes for the E_{140} trap, a conclusion was drawn that the trap is of acceptor nature with the energy level at about $E_c - 0.21$ eV.

Let us consider now the possible origin of the defects, which can be formed upon E-centre annealing at 125–175°C. Fig. 2 shows changes in trap concentrations upon isothermal annealing at 175°C of an electron-irradiated sample with initial resistivity of 1 Ω cm. As it was mentioned above, a significant decrease in E-centre concentration is accompanied by a decrease in concentration of C_i-C_s complexes and by the formation of a defect with an acceptor level at $E_c - 0.21$ eV (E_{140}). Practically a one-to-one anti-correlation in concentration of annealed C_i-C_s complexes and created E_{140} complexes was observed. This suggests that the E_{140} complex is formed at the expense of C_i-C_s complexes. PL measurements also showed a significant decrease in intensity of the G line upon annealing at 125–175°C. Similar results on annealing of the G line were obtained earlier for FZ-Si samples, which were irradiated with gamma-rays from a ⁶⁰Co source [13].

The C_i-C_s complex is known to be stable up to about 250°C [12]. So, two possible mechanisms of the decrease in its concentration in the temperature range 125–175°C can be considered. Firstly, if the main mechanism of the E-centre elimination at about 150°C is its migration as an entity before being trapped, the capture of mobile E-

Fig. 2. Changes in concentrations of defects in an electron-irradiated FZ-Si sample with initial resistivity of 1 Ω cm upon isothermal annealing at 175°C. Fluence of irradiation was $1 \times 10^{15} \text{ cm}^{-2}$.

centres by the C_i-C_s complexes can occur, that can result in the formation of two-carbon-phosphorus complex. No information about existence of such a complex has been reported so far, so the structure and properties of 2C–P defect are uncertain. Secondly, the dissociation of the E-centres upon heat-treatments at 125–175°C can lead to the appearance of free mobile vacancies. The vacancies, upon their motion in the lattice, can interact with the C_i-C_s complexes transforming them into a pair of two substitutional carbon atoms (C_s-C_s). C_s-C_s complex was recently identified by combined EPR, optical absorption and ab initio modelling studies in electron-irradiated carbon-rich Si crystals [14,15]. The main mechanism of the C_s-C_s formation was supposed to be the capture of mobile vacancies by the C_i-C_s complexes [15]. According to the results of Refs. [14,15], the C_s-C_s complex introduces an acceptor level into the upper half of the gap, and there should be an energy barrier for the electron capture into the neutral C_s-C_s complex. All these properties of the C_s-C_s complex are consistent with those found in the present work for the E_{140} trap. In addition the high thermal stability of

the E_{140} trap is consistent with that found for the C_s-C_s [15]. So, it is suggested that the E_{140} trap, which was observed in the present work upon E-centre annealing is related to the C_s-C_s complex. An important consequence of such an identification is that the disappearance of E-centres upon annealing at about 150°C should be associated with their dissociation.

It should be noted that the magnitude of the decrease in the C_i-C_s concentration was only about a half of that for the E-centre practically in all the samples we have studied (Fig. 2). So, there should be another trap for mobile P–V or free vacancies, and this trap accounts for almost half of the annihilated E-centres. Except the E_{140} , we have not observed the appearance in significant concentration of any other defects with deep levels in the upper part of the gap upon E-centre annealing. Further studies are required to identify the second channel of the E-centre disappearance.

Summarising, we found that the disappearance of the vacancy–phosphorus complexes upon annealing of electron-irradiated FZ-Si crystals at 125–175°C is accompanied by a significant decrease in concentration of the C_i-C_s complexes, and by formation of a defect with an acceptor level at $E_c - 0.21$ eV. It is suggested that the level is related to a pair substitutional carbon atoms. The C_s-C_s complex is formed when a free vacancy released upon E-centre annealing is captured by the C_i-C_s complex.

Abstract

Oxygen-doped Ge has been irradiated with 2 MeV electrons and isochronally annealed between 80°C and 440°C. Local vibrational mode absorption at 525.5, 780.9 and 817.9 cm⁻¹ is assigned to three modes of the oxygen dimer. The wave number positions are in excellent agreement with corresponding modes in Si and with published ab initio calculations. The enhanced formation of dimers and thermal donors (TD), due to irradiation and the sequential annealing of dimer and early TD bands, support the model of the dimer as the first agglomeration step preceding TD formation. Two absorption bands at 621.6 and 669.1 cm⁻¹ are assigned, respectively, to the neutral and negative charge state of the A-centre (VO) in Ge. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Germanium; Thermal donor; Irradiation; Oxygen dimer

1. Introduction

The oxygen dimer should be the first oxygen agglomeration step preceding thermal donor (TD) formation in Si and may represent the fast diffusing species explaining the kinetics of TD formation. The dimer in Si is experimentally accessible through the local vibrational mode (LVM) absorption spectrum and four modes seem to be well-established [1,2]. Several papers have been published on the calculation of stable dimer configurations as well [2–4]. In Ge, where oxygen related defects have been less extensively studied than in Si, striking similarities with Si are found for all oxygen related defects identified so far [5]. In our previous study of LVM absorption from TDs in Ge [6], the attention was drawn to weak absorption bands at 780 and 818 cm⁻¹ that always appear in oxygen-doped Ge submitted to a dispersion quench, together with small traces of TD1 and TD2 as detected in the far-infrared electronic absorption spectrum. This is indicative of the

formation of relatively simple oxygen clusters during rapid cooling from high temperature, so the peaks mentioned seemed good candidates for the oxygen dimer in Ge. This assignment seemed substantiated by the almost perfect scaling from the positions of dimer bands in Si [6]. Ab initio calculations by Coutinho et al. [2] predict four modes for the staggered dimer in Ge. The latter consists of two Ge–O–Ge units sharing one Ge and would be the stable dimer form [2].

Here, we report on the LVM absorption in oxygen-doped Ge after irradiation and subsequent isochronal annealing. The primary purpose of the treatments (irradiation, isochronal annealing) was to increase the assumed LVM absorption from the dimers and to follow the evolution into the temperature range of early TD formation. An increased dimer concentration would also favour the observation of other, possibly weaker dimer bands.

2. Experimental

Before irradiation, the oxygen-doped Ge was submitted to a 5 min dispersion at 900°C followed by a

*Corresponding author. Tel.: +32-9-264-4369.

E-mail address: piet.vanmeerbeek@rug.ac.be (P. Vanmeerbeek).

quench to room temperature (RT). The interstitial oxygen concentration measured after the quench was $[O_i] = 2.9 \times 10^{17} \text{ cm}^{-3}$ as determined from the amplitude of the 856 cm^{-1} band (RT), using the conversion factor $[O_i] = \alpha_{\text{max}} \times 10^{16} \text{ cm}^{-2}$ with α_{max} the amplitude in cm^{-1} [7]. The Ge was irradiated with 2 MeV electrons to a fluence of $5 \times 10^{17} \text{ cm}^{-2}$, the temperature during irradiation was kept close to RT. Isochronal anneals of 20 min in the temperature range 80–440°C (increments of 40°C) were performed in the flowing argon. The infrared spectra were recorded at RT, 80 K and 6 K using a nominal resolution of 1 and 0.25 cm^{-1} . The electron concentration was monitored by resistivity and Hall-effect measurements at RT.

3. Experimental results and discussion

The infrared absorption spectra measured after different treatments (quenched, irradiated and annealed) are summarised in Fig. 1. The wave number range corresponds to the LVM range below the O_i peak at 862.3 cm^{-1} . The results are in general agreement with the old data [8,9], however, the improved resolution and sensitivity allow to detect components or weak bands not reported before. In agreement with our earlier experiments [6], two small peaks at 780.3 and 817.9 cm^{-1} are seen in the quenched sample. After the irradiation, a large number of LVM peaks appear, the O_i peak having diminished to 89% of its original amplitude. The evolution of the spectrum during annealing shows that new defects are formed while others disappear. A Ge

reference sample without oxygen doping showed no LVM peaks after irradiation or subsequent annealing. These results indicate that all LVM bands observed should be oxygen related and are probably due to defects containing at least one oxygen atom. In the later annealing stages, the absorption evolves into the LVM bands due to TDs designated before as “600”, “740” and “780”, which refers to their average position at RT [6]. After the 440°C treatment, the amplitude of the O_i peak has decreased further to 74%. On the whole, we observed 64 LVM absorption peaks in the wave number range between 515 and 910 cm^{-1} , of which 23 belong to the TDs [6,10]. The other peaks may be cataloged in at least seven different groups according to their different annealing behaviour. In this paper, the discussion is limited to absorption bands related to the oxygen dimer, the TDs and the VO defect (A-centre).

3.1. Oxygen dimer

As shown in Figs. 1 and 2, the peaks at 780.3 and 817.9 cm^{-1} , that we tentatively attribute to the dimer, become stronger during electron irradiation, grow further during annealing towards 200°C and disappear after the 320°C treatment. It is clear from Fig. 2 that the annealing of the two peaks is identical. In Fig. 2, other bands have been included that show a similar annealing curve and may be considered candidates for other dimer modes. The correspondence with the two major bands is the best for the bands at 525.5 and 766.0 cm^{-1} , while the 572.9 and 801.2 cm^{-1} bands show a somewhat different curve or annealing temperature. We thus end up with

Fig. 1. Infrared absorption spectra of oxygen-doped Ge at 5 K and resolution 1.0 cm^{-1} , after different treatments. The isochronal annealing temperature in $^\circ\text{C}$ is indicated with the graphs. The spectra are vertically shifted, lattice absorption has been subtracted.

Fig. 2. Isochronal annealing curves of LVM bands attributed to VO and to the oxygen dimer; 0°C corresponds to the as-irradiated material.

Table 1
Comparison of experimental positions (cm^{-1}) of LVM bands due to oxygen defects in Ge and Si (low temperature values)^a

	Si	Ge	Factor
O_i	1136.0	862.5	1.32
	1059.8 [10]	817.9	1.30
	—	(801.2)	—
	1012.4 [10]	780.3	1.30
O_2	—	766.0	—
Dimer	—	(572.9)	—
	690.1 [10]	525.5	1.31
	555.8 [10]	—	—
VO^0	835.6 [12]	621.6	1.34
VO^-	885.3 [12]	669.1	1.32

^a Values in the last column give the ratio of Si to Ge positions. Positions within brackets indicate bands for which assignment to the dimer is doubtful.

four preferential candidates for the dimer-related LVM bands in Ge, as summarised in Table 1.

More evidence to assign the bands may be obtained from a comparison with the observed dimer peaks in Si. A scaling factor of about 1.32 for oxygen modes in Ge with respect to Si may be predicted from the relative positions of the ν_3 mode of O_i in the two semiconductors. As shown in Table 1, three of the four modes selected have a counterpart in Si with a scaling factor very close to 1.32. Scaling of the lowest dimer mode of Si at 555.8 cm^{-1} predicts a mode around 420 cm^{-1} in Ge, however, in a wave number range where clear detection of small bands is difficult. On the other hand, no counterpart of the 766.0 cm^{-1} mode seems to exist in Si, throwing doubt on its correlation with the oxygen dimer.

Comparison of our experimental data with the calculated values for the staggered dimer in Ge in Ref. [2] results in an excellent agreement for the upper three dimer modes. The experimental modes at 525.5 , 780.3 and 817.9 cm^{-1} agree within only 2–4% with the calculated modes at 517 , 749 and 784 cm^{-1} . It may also be remarked that contrary to the situation in Si, the dimer bands in Ge display a normal temperature shift expected for LVMs.

3.2. Thermal donors

In Fig. 3, the annealing curve for the dimer is plotted together with those of the first three TDs. In order to compare integrated absorption also (i.e. concentration), results have been plotted for LVMs in a similar wave number range, i.e. the 525.5 cm^{-1} band for the dimer

Fig. 3. Sequential appearance of oxygen dimer and thermal donor bands during annealing. The TD curves plotted represent the total absorption of a TD species in the “600” band, e.g. the sum of the neutral and double donor state absorption.

and the LVM lines in the “600” range for TD1, TD2 and TD3. The figure shows that the dimer appears in a sequence preceding the early TDs. This sequential appearance also seems to support our earlier identification of TD2 with a complex with four oxygens [6], which would imply that TD1 fitting between the dimer and TD2 would probably contain three oxygens. An interesting observation is that in the irradiated Ge, LVM from the TDs becomes visible in the “600” range already after 20 min annealing at $200\text{--}240^\circ\text{C}$. Even if a detailed comparison with the 350°C isothermal anneals of our previous study is difficult [6], it is obvious that the irradiation enhances not only the dimer concentration but also the TD formation. This seems logical if both kinds of defects would belong to the same agglomeration sequence. The presence of simple irradiation defects probably favours the oxygen agglomeration [10].

3.3. VO (A-centre)

In the as-irradiated Ge, the most prominent peak occurs at 621.6 cm^{-1} . It was attributed before by Whan [8] to the A-centre. A second prominent peak annealing out at the same temperature of $160\text{--}200^\circ\text{C}$ (Figs. 1 and 2) and that was not reported before, is observed at 669.1 cm^{-1} . This reminds of Si where the LVM of VO^0 and VO^- may be observed simultaneously depending on the resistivity. From our electrical data we calculate that the Fermi level is situated around $E_C - 0.25\text{ eV}$ during the annealing stages at which the two peaks are observed. Comparing this with the position of the VO-acceptor level in Ge at about $E_C - 0.25\text{ eV}$ [11], it seems reasonable to conclude that in our case, both charge states are also simultaneously present. Comparing again the positions of the corresponding bands in Si and Ge, we find once more a

scaling factor close to 1.32 for both peaks (Table 1). We accordingly assign the bands at 621.6 and 669.1 cm^{-1} to the anti-symmetric stretching LVM of the VO^0 and VO^- centre in Ge, respectively.

4. Conclusion

A major result of this study concerns the observation of LVM bands at 525.5, 780.9 and 817.9 cm^{-1} which are assigned to the oxygen dimer in Ge. The positions are in excellent agreement with observed counterparts in Si and with *ab initio* calculations. The enhancement of the formation of both the dimer and the early TDs as a consequence of irradiation, as well as their sequential appearance during isochronal annealing, strengthen the model of the dimer being a precursor of the TDs. Whether this also implies that the oxygen dimer in Ge represents a faster diffusion species than oxygen interstitials is less obvious, regarding the high diffusion coefficient of the latter in Ge [5]. A new band has been observed at 669.1 cm^{-1} with similar annealing as the band at 621.6 cm^{-1} due to the A-centre. The assignment of the bands to VO^- and VO^0 , respectively, is in agreement with the positions of similar bands in Si and with electrical data.

Experiments are in progress using ^{18}O -doped Ge in order to confirm the above assignments.

Abstract

We discuss the broadening of ground-state to bounded excited-state transitions of shallow donors in strongly compensated n-type Ge:(As,Ga) in the presence of electric fields and their gradients, arising from randomly distributed ionized impurities. Quantitative comparison of the experimentally obtained linewidths with Monte Carlo simulation results makes possible, a unique determination of the ionized impurity distribution in the samples. We present clear evidence for the random-to-correlated transition of the ionized impurity distribution as a function of the ionized impurity concentration and of temperature. © 2001 Published by Elsevier Science B.V.

Keywords: Impurity distribution; Compensated semiconductor; Impurity absorption

Many-body Coulombic interactions between randomly distributed positive and negative charges play important roles in a wide variety of physical systems. Such interactions become important especially when the charges are mobile and redistribute themselves in order to minimize the total Coulombic energy of the system. In this paper, it is demonstrated that the quantitative comparison of the experimental donor 1s–2p_± hydrogenic absorption linewidths and Monte Carlo simulations lead to an unambiguous determination of the ionized impurity distribution as a function of the ionized impurity concentration (N_I) and the temperature (T).

It has been expected theoretically that the ionized impurity distribution is correlated when the available thermal energy is sufficiently smaller than the correlation energy [1,2]. Electrons distribute themselves among donors in such a way as to reduce the total Coulombic energy, i.e., an energy gap known as “Coulomb gap” appears at the Fermi level in the density of the states of the donor band [3]. The correlated distribution is expected to dominate for the condition [1–3]

$$N_I = 2K \left(\frac{k_B T \kappa}{e^2} \right)^3 \quad (1)$$

with κ is the dielectric constant, K is the compensation ratio. The correlated distribution of the ionized impurities has been confirmed for the condition given by Eq. (1) in p-type Ge in our previous study [4].

When the thermal energy becomes larger than the correlation energy, electrons will be randomly distributed among donors, and the ionized impurity distribution is completely random. The random distribution is preferred for lower N_I since the larger distance between ions leads to weaker correlation. Larsen’s classic theory for the calculation of the linewidth assuming the random distribution is valid for the range [5,6]

$$N_I \leq 0.7 \times 10^{-5} a^{*-3}, \quad (2)$$

where a^* is the effective Bohr radius of donor impurities in units of cm.

The experimental determination of the transition temperature allows us to estimate the value of the correlation energy. The correlation energy (or equivalently the width of the Coulomb gap) becomes larger with increasing ionized impurity concentration N_I . While there have been many experiments to confirm the existence of the Coulomb gap, there has been very

little direct evidence for the random distribution of ionized impurities at low temperatures in semiconductors.

For our studies, we cut samples from a CZ-grown, n-type Ge:(As,Ga) single-crystal ingot. The concentrations of As and Ga vary as a function of the position along the ingot growth direction due to impurity segregation during growth. We have obtained a series of samples from various positions of the ingot and determined the concentrations N_D and N_A of As and Ga, respectively, using variable-temperature Hall effect measurements. The infrared absorption spectra were recorded with a BOMEM DA-8 Fourier transform spectrometer. The signal-to-noise ratio was improved by coadding 100–720 spectra. A composite silicon bolometer operating at $T = 4.2$ K was used as a detector. The samples were cooled in the OXFORD OPTISTAT cryostat and the sample temperature was monitored with a calibrated thermometer installed at the sample mount. A 0.1 μm black polyethylene film was placed in front of the samples to eliminate the above band-gap radiation.

The inset of Fig. 1 shows the absorption spectrum of a sample having $N_D = 3.03 \times 10^{13} \text{ cm}^{-3}$, $N_A = 1.75 \times 10^{13} \text{ cm}^{-3}$, i.e., $N_I \approx 2N_A = 3.50 \times 10^{13} \text{ cm}^{-3}$. The spectrum has been recorded at $T = 4$ K with a resolution of

Fig. 1. The main frame shows the enlargement of the $1s-2p_{\pm}$ (100 cm^{-1}) absorption peak determined experimentally (\circ), calculated assuming random (\square) and correlated (\triangle) distributions of ionized impurities using the Monte Carlo method. The solid curves are the best fits to the experimental and calculated points assuming Lorentzian distributions. The inset shows As-donor absorption peaks recorded at $T = 4$ K with a sample having $N_I = 3.50 \times 10^{13} \text{ cm}^{-3}$. The three absorption peaks correspond to the As donor $1s-2p_0$ (76 cm^{-1}), $1s-2p_{\pm}$ (100 cm^{-1}), and $1s-3p_{\pm}$ (106 cm^{-1}) transitions.

0.026 cm^{-1} in the wavenumber range between 70 and 110 cm^{-1} . Three distinct peaks correspond to transitions of bound electrons of As in Ge from the $1s$ ground state to $2p_0$, $2p_{\pm}$, and $3p_0$ excited states, respectively. The main frame of Fig. 1 shows, from bottom to top, the enlargement of the $1s$ to $2p_{\pm}$ transition peaks; the experimental result (open circles), a Monte Carlo simulation assuming a random distribution of ionized impurities (open squares), and a Monte Carlo simulation assuming a correlated distribution of impurities (open triangles). The solid curves are Lorentzian fits to each set of data.

Fig. 2 shows FWHM vs. N_I at $T = 4$ K. The experimental data (filled circles) are compared with the theoretical linewidths assuming random (dashed line) and correlated (solid line) distributions of the ionized impurities. The intrinsic linewidth due to phonon lifetime broadening [7] for Ge has been found, experimentally, to be 0.066 cm^{-1} [8], which is negligibly small compared to the linewidths shown. Also $N_D < 1 \times 10^{15} \text{ cm}^{-3}$ for all of the samples employed, i.e., the broadening due to overlap of donor wavefunctions (concentration broadening) is negligible compared to the amount of electric-field broadening [9]. Therefore, it is appropriate to compare the experimentally found FWHM directly with the calculated widths assuming only an effect of the electric-field broadening. The comparison between the experimental results and theoretical estimates leads us to very interesting conclusions. Excellent agreement between the experimentally determined FWHM and the random theory for $N_I < 7.5 \times 10^{13} \text{ cm}^{-3}$ is clear evidence for the random distribution of ionized impurities in this low N_I region. When N_I is larger than $7.5 \times 10^{13} \text{ cm}^{-3}$, the experimental

Fig. 2. Experimentally determined FWHM (filled circles) vs. N_I at $T = 4$ K. The dashed line is the prediction based on a random distribution of ions, while the solid line is the prediction based on a correlated distribution of ionized impurities at zero temperature.

data lie between the estimates of random theory and correlated theory. This implies that the ionized impurity distribution is somewhere between “completely random” and “completely correlated”. The Monte Carlo simulation for the correlated distribution shown in Fig. 2 has been performed for $T = 0$ K. However, the measurement was performed at finite temperature ($T = 4$ K) at which a certain degree of randomization of ionized impurities occurs due to the finite thermal energy. In this case, we expect the linewidth to have a value between the prediction of “completely random” and “completely correlated” distribution. Fig. 3 shows the comparison of the linewidths between $T = 4$ and 10 K. As expected, the linewidths at 4 and 10 K for the “completely random” region ($N_I < 7.5 \times 10^{13} \text{ cm}^{-3}$) are

Fig. 3. Experimentally determined FWHM vs. N_I at $T = 4$ (●) and 10 K (▲).

the same while that of 10 K is broader than 4 K due to the larger degree of thermal randomization of the ionized impurity distribution. The critical ionized impurity concentration (N_{IC}), where the change of slope occurs in Fig. 3, shifts from $7.5 \times 10^{13} \text{ cm}^{-3}$ at $T = 4$ K, to $1.0 \times 10^{14} \text{ cm}^{-3}$ at $T = 10$ K. Eq. (2) predicts $N_{IC} = 1 \times 10^{13} \text{ cm}^{-3}$ for Ge at $T = 0$ K. Considering the fact that N_{IC} shifts to larger values for $T > 0$ K, the experimentally observed $N_{IC} = 7.5 \times 10^{13} \text{ cm}^{-3}$ at $T = 4$ K should be considered to be in excellent agreement with the prediction of Eq. (2). Fig. 4 shows the temperature dependence of the FWHM (■) for a sample having $N_I = 7.8 \times 10^{13} \text{ cm}^{-3}$, which is just above the critical concentration $N_{IC} = 7.5 \times 10^{13} \text{ cm}^{-3}$ for $T = 4$ K. We are interested in whether we observe a random to correlated transition with temperatures increasing from $T = 2$ K. Fig. 4 shows clearly that the FWHM increases in two steps; the first gradual increase occurs between $T = 5$ and 11 K and the second rapid increase takes place above $T = 14$ K. The second increase at $T > 14$ K is due to thermal ionization of donors as it matches with the increment of N_I (solid curve). The first gradual increase is due to the transition of the ionized impurity distribution from correlated to random, and the two plateaus in FWHM at $T = 2$ –5 K and 11–13 K represent characteristic FWHM for the two distributions. In order to support our claim that we have observed the transition, we shall estimate the critical temperature (T_c), for the transition, using the theory of Efros and Shklovskii and compare the result directly with our experimental observation. The energy of the Coulomb gap Δ for three dimensions is approximately [3];

Fig. 4. The main frame shows FWHM vs. temperature for a sample having $N_I = 7.80 \times 10^{13} \text{ cm}^{-3}$. The solid curve is the ionized impurity concentration calculated with Eqs. (3) and (4). The inset shows the FWHM vs. temperature of three samples having $N_I = 4.32 \times 10^{13}$ (▲), 7.80×10^{13} (■), and $2.26 \times 10^{14} \text{ cm}^{-3}$ (▼).

$$\Delta = e^3 g_0^{1/2} / k^{3/2}, \quad (3)$$

where g_0 is the density of states at the Fermi level and can be estimated with

$$g_0 = KN_D k r_D / e^2. \quad (4)$$

$r_D = (3/4\pi N_D)^{1/3}$ is the distance between donors. Using Eqs. (3) and (4), $\Delta = 0.31$ meV has been obtained for the sample having $N_I = 7.8 \times 10^{13} \text{ cm}^{-3}$ in Fig. 4. To first order, we expect T_c to be of the same order as Δ , i.e., $T_c \approx 3.6$ K is what we estimate, based on theory. The experimentally found gradual increase starts around 4 K, in very good agreement with the theoretically estimated $T_c \approx 3.6$ K. The inset in Fig. 4 shows the temperature dependence of the FWHM for samples well below N_{IC} and well above N_{IC} . The width of the bottom curve ($N_I = 4.3 \times 10^{13}$) remains unchanged because its width is determined solely by the random distribution all the way up to 12 K. Above 12 K, the ionization of donors takes place and the peak disappears very quickly, i.e., it was not possible to determine the widths in this high temperature region. The FWHM of the bottom curve ($N_I = 4.3 \times 10^{13}$) for the temperature range 2–12 K agrees very well with the theoretical prediction of the random theory (the dashed line in Fig. 2). The FWHM of the top curve in the inset ($N_I = 2.26 \times 10^{14}$) for the temperature range shown is determined dominantly by the correlated distribution because the donor concentration is high enough for the neighboring ionized impurities to interact with one another. The FWHM increases with the increasing temperature because the partial randomization of the correlated distribution proceeds as was shown in Fig. 3.

Observation of the random-to-correlated transition of ionized impurity distributions as a function of tempera-

ture has been claimed before by Baranovskii et al. for GaAs [10–13]. However, analysis of their data shows that they observe an increase of FWHM due to ionization of donors and not due to the transition. As one can see in the inset of Fig. 4, it takes extreme fine-tuning of N_D and N_A in order to observe a clear signature of the transition with two distinct plateaus below the temperatures where ionization takes place. The precise control of both donors and acceptors at the level of 10^{13} cm^{-3} has been the key for the successful observation of the random-to-correlated transition of the ionized impurity distribution in semiconductors.

Abstract

Results are presented of implantation and diffusion study of boron (B) in germanium (Ge). B implantation was carried out in Ge with different energies and to different doses. High-resolution secondary ion mass spectroscopy was used to obtain concentration profiles after furnace annealing. The as-implanted profiles show a long tail possibly due to enhanced diffusion. A limited diffusion has been observed after furnace annealing. Using T-SUPREM, diffusivity value of $1.5(\pm 0.3) \times 10^{-16} \text{ cm}^2/\text{s}$ at 850°C has been extracted. This value is two orders of magnitude lower than previously reported values. The results question the change in diffusion mechanism of B diffusion in Si–Ge alloys from low Ge levels to high Ge levels. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Germanium; Boron; Ion implantation; Diffusion

1. Introduction

Potential application of silicon germanium (Si–Ge) alloys in HBTs, HFETs, and optoelectronic devices has motivated dopant diffusion studies in these alloys. The dominance of interstitials in diffusion of B in Si is well established from various studies [1] while recent defect injection studies confirm the same interstitially mediated diffusion in Si–Ge alloys up to 20% Ge [2]. Compared to Si, very little experimental work has been carried out in pure Ge or Si–Ge at high Ge levels. There are only two reports [3,4] of B diffusion in Ge which themselves disagree in diffusivity value by two orders of magnitude. Motivated by lack of knowledge of B diffusion in Ge and availability of better characterization techniques, along with ion implantation as method of introducing known amount of B, diffusion behaviour of B in Ge is studied. Furnace annealing is carried out and diffusivity

values have been calculated by fitting the experimentally obtained profiles.

2. Experimental procedure

Germanium single crystals, polished either on one or both sides with diameters 2" and 4" and a thickness of 300 μm were supplied by Eagle-Picher technologies, USA. The wafers were $\langle 111 \rangle$ and $\langle 100 \rangle$ oriented, n doped ($\leq 0.4 \Omega\text{cm}$) or undoped ($> 30 \Omega\text{cm}$). Dislocation density of all wafers was less than 5000/ cm^2 . Wafers were cleaned with fuming nitric acid followed by rinsing in de-ionized (DI) water. ^{11}B ions were implanted into the polished side of the wafers with 5 and 20 keV to different doses ranging from 5×10^{13} to 6×10^{14} ions/ cm^2 . The ion beam was misoriented by 8° to the normal of the wafers. A silicon dioxide (SiO_2) layer was deposited on the implanted side of the wafers. This layer had two-fold function of protecting the vulnerable Ge surface during high temperature annealing and avoiding any out-diffusion of B atoms. The SiO_2 layer

*Corresponding author. Tel.: +44-2380-592351; fax: +44-2380-593016.

E-mail address: suresh@soton.ac.uk (S. Uppal).

was deposited by plasma enhanced chemical vapor deposition method at a temperature of $\sim 200^\circ\text{C}$ and had a thickness of approximately 2000 \AA . The samples were cleaned ultrasonically in DI water and methanol before annealing. Furnace annealing was carried out for temperature range $675\text{--}850^\circ\text{C}$ ($\pm 3^\circ\text{C}$) for different times. A reducing atmosphere of forming gas [a mixture of H_2 (5%) and N_2] flowing at a rate of 1 L/min was ambient for diffusion experiments. The SiO_2 layer was etched away using a standard HF etch after annealing. For determining the depth profiles an Atomika 4500 secondary ions mass spectroscopy instrument was used. A primary beam of oxygen (O_2^+) ions was used with 500 eV energy and at an angle of 25° to the normal of the wafer surface. An error of 10% can be associated with depth and concentration quantification from the raw SIMS data. A surface degradation was observed on annealing at higher temperatures and for longer times which made depth profiling using SIMS very difficult.

3. Results and discussions

Preliminary experiments were performed with implantation dose up to $5 \times 10^{14}\text{ ions/cm}^2$. The annealing carried out in forming gas ambient for temperatures up to 800°C for 24 h did not show any noticeable B movement from the as-implanted profile. Subsequently the temperature was raised to 850°C . A limited movement towards the end of the profiles was observed after annealing for 24 h. The profiles so obtained were analyzed quantitatively for diffusivity.

The measured boron profiles for implantation with two different energies of 5 and 20 keV in $\langle 111 \rangle$ Ge are presented in Fig. 1. The implantation dose used in each case is indicated in the figure. It also shows the profiles obtained from theoretical projected range and standard deviation values given by Gibbons et al. [5] using LSS calculations. Note that the values for 5 keV implant have been obtained by extrapolation. Similar implantation tails were observed for 5 and 20 keV implants in $\langle 111 \rangle$, and 20 keV implant in $\langle 100 \rangle$ direction. Comparing the peak concentration positions and theoretical values, we observe rough agreement in projected range although an implantation tail could be seen in all the as-implanted profiles. The implanted profiles were fitted using T-SUPREM assuming a dual-Pearson distribution. The parameters for fitting the as-implanted profiles were estimated from the experimentally obtained depth profiles. With 80% dose allocated to amorphous profile and 20% to channeling, the as-implanted profiles could be fitted very well. Similar tails have been observed for implanted B in Si where predominant contribution to the tail is from channeling. However, other implantation studies [6,7] have emphasized *radiation-enhanced diffusion* as dominant during B implantation in Ge at low

energies. The contribution of channeling, as obtained from fitting the implanted B profiles, is only 20% and thus it appears that enhanced diffusion is mainly responsible for the tails observed in our case as well.

The limited B diffusion was also analysed using T-SUPREM, which, as discussed above, could achieve a fit to the as-implanted profiles. These fitted profiles were taken as initial conditions for the diffusion calculations. The diffused distributions so obtained were compared to diffused SIMS profiles (850°C , 24 h) for the best fits to obtain values for solid solubility and diffusion coefficient, which were taken as parameters. For n type $\langle 111 \rangle$ Ge, $4.5 \times 10^{18}/\text{cm}^3$ and $1.8 \times 10^{-16}\text{ cm}^2/\text{s}$ values were obtained for solid solubility and diffusion coefficient, respectively. The values used for best fit of diffused profile for n type $\langle 100 \rangle$ were $6.5 \times 10^{18}/\text{cm}^3$ and $1.3 \times 10^{-16}\text{ cm}^2/\text{s}$ for solid solubility and diffusion coefficient, respectively. The experimental as-implanted and diffused profiles along with the fitted profiles are shown in Fig. 2. The solid solubility values agree with the values reported in literature [8]. The diffusivity calculation for $\langle 111 \rangle$ and $\langle 100 \rangle$ are also consistent. However, these diffusivity values are at least two orders of magnitude smaller than the minimum values reported in literature [9,10]. Hot probe measurements were also performed on samples as implanted and after heat treatment. Samples implanted with low dose were noticed to have a p–n junction formation in as-implanted state. However complete electrical activity for all doses studied could be observed only after the heat treatment.

Fig. 1. Concentration profiles of as implanted B in $\langle 111 \rangle$ Ge for different energies. Also shown are the profiles obtained using LSS calculations for the two energies. The projected range and projected standard deviations for 5 keV implant were extrapolated from the data Gibbons et al. [5].

Fig. 2. SIMS B depth profiles of as implanted ($6 \times 10^{14}/\text{cm}^2$, 20 keV) and annealed (850°C, 24 h) sample. Using T-SUPREM, the best fit to diffused profile gave a diffusivity value of $1.3 \times 10^{-16} \text{ cm}^2/\text{s}$ for $n < 100$ Ge.

Various possibilities for the large discrepancy between the diffusivity values of this work and previous studies have been highlighted in a previous report [10]. It is important to note that the previous studies [3,4] were carried out by p–n junction and profiling by sheet resistance, rather than the SIMS profiling of total B in the present work. The possible cause for an immobile peak is precipitation of excess B since the solid solubility limit of B is crossed. The slower diffusion could be due to pairing/trapping of B with the implantation-induced defects (e.g. self-interstitial) however, Fang et al. [11] have shown that Arsenic implantation enhanced B diffusion in Si–Ge. The SiO_2 layer is believed to introduce point defects in Si which affects dopant diffusion. The presence of a SiO_2 layer on Ge surface might as well influence the dopant diffusion by injecting defects. Further studies are being carried out to resolve these issues.

B diffusivity as a function of Ge content for strained and relaxed Si–Ge obtained by various workers [11–15] is presented in Fig. 3. The diffusivity for strained as well as relaxed Si–Ge decreases rapidly with Ge content up to about 40% Ge. No consensus on the cause for this decrease in diffusivity has been reached. For Arsenic implantation in Si–Ge, a decrease in implantation-induced enhancement of B diffusivity with increase in the Ge concentration has been reported [11]. Based on a simple implantation-enhancement model, increase in the concentration of interstitials in thermal equilibrium with increase in Ge percentage has been hypothesized. Recent defect injection studies [2] have already shown that the mechanism responsible for B diffusion in Si–Ge alloys is interstitially mediated. Fang et al. [11] have concluded

Fig. 3. Boron diffusivity as a function of Ge composition in Si–Ge alloys. Values for relaxed Si–Ge are for 800°C, other values being at 850°C. Our diffusivity value corrects the previous values by two orders of magnitude in pure Ge.

that decrease in the mobile B diffusivity, and not decrease in interstitial concentration, causes much of the decrease in B diffusivity in Si–Ge alloys with Ge content. This model also implies that it is unlikely that at high Ge levels diffusion of B will be dominated by vacancies as previously assumed for most Group III elements in Ge. Our present measurements suggest, in fact, that at Ge levels above 50%, there is at most a very small increase in diffusivity with Ge content (see Fig. 3), and imply no sharp change as assumed previously. Experiments are being carried out to answer these questions by better understanding of B diffusion process in pure Ge.

4. Summary

Boron implantation in Ge has resulted in profiles which differ from LSS calculation in terms of an implanted tail. The observed tails could be a result of radiation-enhanced diffusion. A slow diffusion for implanted B is observed. The diffusivity value has been calculated to be $1.5(\pm 0.3) \times 10^{-16} \text{ cm}^2/\text{s}$ at 850°C from the fitting of the diffused profiles which correct the previous values reported by at least 2 orders of magnitude. The cause for this slow diffusion is not directly apparent. Nevertheless, this new measurement suggests that there is little increase in B diffusivity from 50% to 100% Ge and calls into question the previously accepted view that the interstitially dominated diffusion

at low Ge level changes to a vacancy dominated mechanism at high Ge level.

Vacancies and self-interstitials in germanium: a picture derived from radioactive probes

R. Sielemann^{a,*}, H. Hässlein^a, Ch. Zistl^a, M. Müller^a, L. Stadler^a, V.V. Emtsev^b^a *Hahn-Meitner-Institut Berlin GmbH, Glienicker Strasse 100, 14109 Berlin, Germany*^b *Joffe Institut St. Petersburg, Russia*

Abstract

Several experimental methods based on radioactive probes have been used and combined to study vacancies and self-interstitials in Ge. Central to the studies is the perturbed angular correlation spectroscopy. Defects are created and detected by electron irradiation with subsequent trapping at ^{111}In probe atoms and the neutrino-recoil technique. From combination of both types of techniques defect identification is achieved and numerous microscopic defect parameters of the isolated defects and defect–impurity pairs are extracted. Additional information on electrical levels is obtained by applying deep level transient spectroscopy (DLTS) to samples containing radioactive ^{111}In probes (radiotracer-DLTS). © 2001 Elsevier Science B.V. Keywords: Germanium defects; Perturbed angular correlation; Deep level transient spectroscopy

1. Introduction

Though point defects in Ge have attracted intensive research for a long time and numerous results have been obtained, mostly by electrical and capacitance techniques [1,2], no microscopic identification of either vacancy or self-interstitial has yet been accomplished. Thus, a definite assignment of the collected data to the respective defects is still missing and interpretation of the results has remained largely speculative. It is clear, however, that a better knowledge would be of considerable interest not only for Ge itself but also with respect to Si for which a large amount of definite data exist [3].

Recently, another approach to identify and study the intrinsic defects in Ge has been presented. Several experimental techniques based on the radioactive probe nuclei have been employed. Primarily, the perturbed

angular correlation (PAC) technique has been used which is based on the fact that defects in the immediate vicinity of a radioactive probe atom (^{111}In) can be studied via the induced hyperfine interaction. In this way, structural and electronic defect properties can be obtained. Vacancies and self-interstitials were produced either by electron irradiation or by using the PAC probe itself as primary knock-on atom (PKA) effected by the emission of a neutrino in a preceding nuclear transmutation. From the combination of both types of experiments, identification of both the vacancy and the self-interstitial is achieved and numerous defect properties are obtained. A further experimental technique used is DLTS applied to Ge samples doped with radioactive ^{111}In probes.

In this contribution, we will first shortly present the experimental techniques. In the following, we list and discuss the properties of the vacancy and self-interstitial and how these properties were extracted from the various experiments. Finally, we touch recent results obtained by other experimental techniques and mention work in progress which calculates the geometrical structure and electronic properties of the relevant defect–probe pairs.

2. Experimental techniques

2.1. Perturbed angular correlation spectroscopy (PAC)

The PAC method is based on the measurement of the nuclear quadrupole interaction of a radioactive probe nucleus with the charge distribution in its immediate environment. The charge distribution yields information on the probe's lattice site and defects, which might be situated around it in the form of an electric field gradient (EFG) tensor. The tensor parameters measured are the strength (frequency) ν_Q , the asymmetry parameter η and the crystallographic orientation which yields microscopic information on the probe-defect structure. In addition, the fraction of probes with a certain defect configuration can be determined. The probe nucleus used throughout the experiments is ^{111}In decaying to ^{111}Cd on which the hyperfine parameters are measured. A recent review of the PAC technique can be found in Ref. [4].

2.2. Defect production by electron irradiation

Vacancies and self-interstitials were produced in two different ways: either by irradiation with 1.2 MeV electrons or by the neutrino recoil technique. In the first case, irradiations of the samples were performed at cryogenic temperatures (in some cases at room temperature) to fluences of typically $5 \times 10^{16} \text{ e/cm}^2$. Following the irradiations, isochronal anneals were performed monitored by PAC to search for trapping at the ^{111}In probes.

2.3. Defect production by neutrino recoil

The direct neighbourhood between probe atom and defect is essential for PAC. A full exploitation of this fact is made by a defect production technique which is centered on the probe atom [5]. This is accomplished by using a probe atom which also serves as PKA. Fig. 1 shows the principle: instead of using ^{111}In as parent activity, the precursor ^{111}Sn is used. In the electron capture decay to ^{111}In a high energy neutrino is emitted which leads to a monoenergetic recoil of 29 eV on the ^{111}In probe. This is an energy close to or above the threshold T_d for single Frenkel pair formation in most materials in immediate vicinity of the ^{111}In probe. For Ge T_d is known to be about 20 eV.

2.4. Deep level transient spectroscopy (DLTS) on radioactive probes

A current weakness of DLTS is the fact that it does not contain information on the chemical nature and microscopic structure of an observed defect. This deficiency makes it difficult to correlate DLTS with

Fig. 1. Partial decay scheme illustrating the neutrino recoil effect. The neutrino emitted in the decay of ^{111}Sn carries an energy of 2.5 MeV leading to 29 eV recoil on the PAC probe ^{111}In .

structure sensitive methods. In recent developments, it was shown that information on the chemical nature can be added by applying DLTS to radioactive atoms [6]. In the present case, we have used samples like those prepared for PAC with radioactive ^{111}In probes subjected to electron irradiation and isochronal anneals. DLTS spectra were measured on these samples during a period of several days covering the decay of ^{111}In ($T_{1/2} = 2.8 \text{ d}$). One expects that the concentration of deep levels related to ^{111}In should decrease and those related to ^{111}Cd increase as function of time.

2.5. Probe production and recoil implantation

All methods described above are based on the incorporation of radioactive probe atoms in Ge [5]. This is done by a recoil implantation technique: A heavy ion beam of high energy (50–100 MeV) produces ^{111}In (or ^{111}Sn) atoms. In this process, the radioactive ions receive recoil energies between 1 and 10 MeV and become well separated from the primary heavy ion beam. The high recoil energies lead to implantation depths of typically 1–5 μm and low probe concentrations: typically between 10^{13} and 10^{14} cm^{-3} . Following implantation, the Ge samples are annealed at slightly above 600°C to remove the implantation damage and relax the probes to substitutional sites. This process is well monitored and leads to completely unperturbed probe incorporation.

3. Experimental results and discussion

3.1. Identification of vacancy and self-interstitial

Combining the results of the neutrino recoil experiments with those from the trapping experiments, identification of vacancy and self-interstitial is possible. In the recoil experiment, ^{111}Sn was implanted in p- and n-type samples with subsequent annealing of the implantation damage. Following this procedure, the probe is cooled to 4.2 K so that the decay of ^{111}Sn to ^{111}In takes place at this temperature. The result is shown in Fig. 2. 11% of the probes display an interaction frequency $\nu_{Q1} = 54 \text{ MHz}$ with axial symmetry ($\eta = 0$), showing that a defect is present at the probe. From additional experiments, the orientation of the probe-defect complex can be inferred to be in a $\langle 111 \rangle$ direction. This defect production is restricted to p-Ge, in n-type and intrinsic material no defect production occurs. Isochronal anneals show that the defect is stable to 205 K [7] and then disappears. Since the threshold for Frenkel pair formation is known to be around 20 eV, only one Frenkel pair, one vacancy and one interstitial can be produced. The probe atom as the PKA can either knock a neighbouring atom out of its site and take its position, leaving a vacancy behind (adjacent to the probe), or it may itself end up in an interstitial position. So the defect (54 MHz) connected with ν_{Q1} must be the association of the probe with a vacancy or represents the probe on some type of interstitial site. Theory has until recently not been able to calculate the EFGs pertaining to specific defect situations with sufficient accuracy, this situation, however, is presently changing [8,9]. Remedy of this ambiguity, however, can be obtained by combining the results from neutrino recoil with those from the trapping experiments described in the following.

Fig. 2. PAC spectrum of $^{111}\text{In}/^{111}\text{Cd}$ measured at 4.2 K after neutrino recoil in p-Ge. The spectrum shows a defect with $\nu_{Q1} = 54 \text{ MHz}$.

Fig. 3. PAC spectrum of $^{111}\text{In}/^{111}\text{Cd}$ and Fourier transform after electron irradiation in p-Ge measured at 293 K. The spectrum shows both ν_{Q1} and ν_{Q2} .

In these experiments, the ^{111}In -implanted and subsequently annealed samples were electron irradiated (mostly at 77 K). Isochronal annealing was executed and monitored by PAC in a range up to several hundred K. These experiments were performed with p-(Ga), n-(Sb) type, and also with high purity material. Depending on doping either one or two defects are trapped at the probes [10]: the already known defect from neutrino recoil (54 MHz) and a second one with $\nu_{Q2} = 420 \text{ MHz}$ ($\eta = 0$ and orientation $\langle 111 \rangle$), Fig. 3. Since $\nu_{Q1} = 54 \text{ MHz}$ occurs in both the recoil and the trapping experiment, the probe has to occupy a position compatible with both types of defect formation. This leaves only the substitutional site for the probe atom and identifies ν_{Q1} with a monovacancy nearest neighbour to the probe. For ν_{Q2} , such an identification is not possible since this defect is not produced by neutrino recoil. From extended series of experiments [10], it could be excluded that unintentional impurity trapping is observed. Thus, by exclusion of that possibility one can associate ν_{Q2} with a self-interstitial trapped at the probe in $\langle 111 \rangle$ direction. Additional corroboration of this identification will be discussed below.

3.2. Electrical properties of vacancy and self-interstitial

Given the above identification of vacancy and self-interstitial microscopic defect parameters can be extracted from the data [10]. The defects' trapping behaviour was studied as function of the carrier concentration (Fermi level) in n- and p-type material, see Fig. 4. The vacancy is observed only in p-Ge, the self-interstitial in p- and n-Ge but not in highly doped material. The entire trapping behaviour can be consistently explained when Fermi level-dependent charge states are assigned to the defects, keeping in mind that the shallow acceptor ^{111}In is always negative (or partly neutral in heavily p-doped material). Trapping of the vacancy in the form shown in Fig. 4 becomes understandable if an acceptor state for V at $E = E_V + 0.20 \text{ eV}$

Fig. 4. Fractions of ¹¹¹In atoms forming complexes with vacancies (squares) and self-interstitials (circles) observed versus carrier concentration in n- and p-type Ge after electron irradiation at 77 K and subsequent warm-up to room temperature.

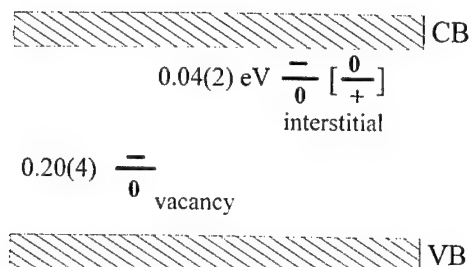

Fig. 5. Electrical levels of vacancy and self-interstitial in Ge as deduced from PAC. For the self-interstitial two options are possible: The acceptor represents the more likely case. see text.

exists, see Fig. 5. This leads to trapping at ¹¹¹In when V is neutral whereas in the negative state no trapping occurs due to Coulomb repulsion. Obviously, the trapping must be caused by elastic interaction between V and the strongly oversized ¹¹¹In atom in the Ge matrix. This reasoning becomes unique when the presence of the Ga dopants are simultaneously taken into account; vice versa with similar considerations, one can infer that the Ga doping atoms, being shallow acceptors like the In probes, do not (or very weakly) interact with Vs. Recent ab initio calculations also place an acceptor level for V in that energy region [11]. This is also in accordance with earlier evidence from electrical measurements [1].

For the self-interstitials' trapping at the probes, the data displayed in Fig. 4 leave two possible scenarios for the interstitials' charge states. Both need a level close to the conduction band, see Fig. 5. If this level were a donor, trapping might be explained as occurring between positive Is and the probes (Coulomb attraction), loss of trapping in highly doped n-Ge would then result from the neutralisation of I. Loss of trapping in p-type Ge would result from competitive Coulomb trapping at the Ga dopants. A second scenario might

assume the level close to the conduction band to be an acceptor. In this case, trapping would take place between neutral Is and the In probes. Loss of trapping in n-material would then result from the Coulomb repulsion when I turns negative. Loss of trapping in p-type Ge either from competitive trapping of the neutral Is with the Ga dopants or due to a second gap state of the Is in the lower half of the band gap which might render Is positive in highly doped material also leads to competitive trapping at Ga. The trapping data alone cannot decide between these two options. Recent ab initio calculations [12] indeed place an acceptor level close to the conduction band, which is also in accordance with earlier more indirect evidence [1]. If we accept that interpretation (scenario 2), an interesting question arises as to the origin of the interaction between a neutral I and a negative In atom while, on the other hand, there is practically no interaction between the Is and the donor dopants (Sb). This question is thoroughly discussed in Ref. [13].

3.3. Kinetic properties of vacancies and self-interstitials

Fig. 6 shows detailed annealing experiments in p-Ge following electron irradiation. Capture of the neutral vacancy and the interstitial (presumably also neutral, see above) occurs in a similar temperature range, 200(10) K for the vacancy and 220(10) K for the interstitial (for 15 min isochronal anneals). From several supporting arguments, we conclude that the capture processes are diffusion limited implying that both defects undergo long range migration with very similar activation energy, about 0.6(1) eV. This finding is somewhat surprising since interstitial migration is often assumed to occur at much lower temperatures. From the annealing behaviour shown in Fig. 6 the binding energy to the In probe can also be extracted: 0.5(1) eV for both I and V. With the given defect identification, the

Fig. 6. Normalised fractions of ¹¹¹In atoms forming complexes with vacancies (squares) and self-interstitials (circles) observed versus annealing temperature after electron irradiation at 77 K in p-Ge.

production and thermal annealing of the neutrino recoil can also be understood. The recoil process leads to a vacancy-associated probe (v_Q) with a defect stability of only 205 K in contrast to the stability of this same pair occurring in the trapping reaction (about 400 K, see Fig. 6). This fact implies that the mechanisms erasing the pair are different: after recoil, the pair is annihilated by the close-by but not visible antidefect, the self-interstitial; after trapping, however, the pair disappears when the vacancy overcomes the binding to the probe and diffuses away. Both, free interstitial trapping (220 K, see Fig. 6) and pair annihilation by the close-by interstitial are rather close in temperature (the latter about 20 K lower) indicating that the processes are diffusion limited and not determined by barriers since eventual barriers should be quite different.

3.4. Electrical level of In–V pair

Since the probe–defect complexes (In–V, In–I, Cd–V, Cd–I) play such an important role in PAC, further electrical and structural information on these pairs is desirable. For electrical information DLTS is useful, however, even though quite a number of studies on radiation-induced defect–impurity pairs exist, interpretation of the data remained more or less speculative. We have, therefore, used DLTS on radioactive ^{111}In probes as described above. In this study, a level in p-Ge at $E = E_V + 0.33\text{ eV}$ decreases in concentration with a half-life of 2.8 d and must, therefore, be related to the ^{111}In probe [14]. From PAC measured on the same sample, we can assign this level uniquely to the In–V defect, which is the only one appearing in the PAC spectra. Since the Cd–V level, into which the In–V level decays, is not observed in these spectra, we conclude that it must be situated in the upper half of the band gap. Levels associated with I are neither observed in p-type nor in n-type material, one reason might be that these levels are too shallow to be detected.

3.5. Structural properties of defect–impurity pairs

Since PAC always measures the properties of defect–probe pairs, structural information on the isolated defects is not directly available. Some information on the defect–probe pairs, however, can directly be gained by PAC-like symmetry properties and crystallographic orientation. This information was used in characterising the Cd–V and Cd–I pair. Another major source of information, the strength of the EFG (coupling constant v_Q) has in the past found little application in determining defect structures since it could not be reliably calculated for comparison with experiment. This situation, however, is about to change. Recently, *ab initio* methods have been used to calculate the geometric structure and resulting field gradients for defects and

defect pairs in semiconductors [8,9]. In the present case, the small electric field gradient (quadrupole coupling $v_Q = 54\text{ MHz}$) obtained for the Cd–V pair has prompted us to suggest that the Cd probe might assume a position in the centre of a divacancy-like configuration (“split-vacancy”) analogous to the Sn–vacancy configuration in Si unravelled by Watkins [3]. This special configuration might also be involved in defect structures measured by PAC in Si [15–17] where defect frequencies in close analogy to Ge appear ($v_Q = 29$ and 451 MHz). Calculations for both Ge and Si are presently on the way [18] and seem to corroborate the identifications given for the vacancy and self-interstitial in the present work.

4. Conclusion

A combination of several experimental techniques based on radioactive probes has been used to study the fundamental defects, vacancy and self-interstitial in Ge. Identification of the defects could be achieved and a variety of microscopic defect parameters determined. Recently, published results obtained with positron annihilation spectroscopy [19] and X-ray techniques [20] confirm the conclusions of the present paper on the kinetic properties of V and I. Newly developed *ab initio* calculations of EFGs will allow to draw detailed structural information from the measured PAC parameters by comparison of experiment and theory in the near future [18].

Abstract

The implantation behaviour of boron in silicon–germanium mixed crystals was studied. The β -NMR technique was used to measure electric field gradients at boron nuclei in defects. In addition, full-potential DFT calculations were performed to allow the interpretation on the basis of calculated bond lengths and electronic densities. Two defects were identified: a boron–germanium pair on lattice site in a relaxed silicon environment and a complex with interstitial boron. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Silicon–germanium crystals; Boron implantation; β -NMR; DFT calculations

Silicon–germanium crystals carry expectations for improved semiconductor devices. Although the phase diagram [1] and the band gaps for different compositions of $\text{Si}_{1-x}\text{Ge}_x$ [2] are known, investigations about growth properties and doping conditions are still relevant. The volume difference between silicon and germanium of about 4% makes it difficult to grow bulk materials in good quality, and the development of acceptors after boron implantation depends on the occupied lattice site. In order to contribute to the knowledge of boron defect centres, we have implanted radioactive ^{12}B into the mixed crystals. Combining β -NMR measurements with full-potential DFT calculations, we were able to identify and characterise two boron defect configurations.

In the experiment, we took advantage of the known nuclear properties of the radioactive ^{12}B isotope and its production process. The nuclear spin of the ground state is $I^\pi = 1^+$. Using 1.5 MeV deuterons in the $^{11}\text{B}(\text{d}, \text{p})^{12}\text{B}$ nuclear reaction on a thin target foil and choosing the appropriate recoil angle of 45° [3], we obtained a 10% polarisation of the nuclear spin in the implanted nuclear ensemble. This polarisation, which is correlated to the asymmetric ejection of electrons in the β -decay of ^{12}B , was detected by two detectors, one on each side of the

reaction plane. The boron-doped crystals were grown by the Czochralski method to make samples with germanium contents between 0% and 7% [4]. In order to be able to align each of the three low-index axes of the cubic lattice parallel to the external magnetic field \mathbf{B}_0 , the single crystals were prepared to have polished (110) surfaces.

In the combined interaction with the external magnetic field and the electric field gradient, the degenerate nuclear level is split with respect to the nuclear magnetic quantum number m . The sublevel position depends on the Larmor frequency ν_L and the quadrupole constant ν_Q which are defined by

$$h\nu_L = -(m/I)\mu\mathbf{B}_0, \quad h\nu_Q = eQV_{zz}. \quad (1)$$

V_{zz} is the greatest eigenvalue of the electric field gradient. For ^{12}B , the nuclear magnetic moment $\mu = 1.002\mu_B$ [5] and the quadrupole moment and its sign $Q = 13.2\text{ mb}$ [6,7] are known.

In the experiment, we frequently made use of transitions between the $m = -1$ and $m = +1$ sublevels, which can be observed if quadrupolar interactions are present. The transition frequency between these levels is calculated from second order perturbation theory [8]:

$$\begin{aligned} \nu_{-1 \leftrightarrow +1} &= 2\nu_L + \delta \\ \text{with } \delta &= (3/8)^2 \sin^2 \theta (3 \cos^2 \theta + 1) \nu_Q^2 / \nu_L. \end{aligned} \quad (2)$$

Here, θ is the angle between the directions of z and B_0 . The angular dependence of δ was used to determine the alignment of the field gradient in the lattice.

There are two configurations which were identified by their quadrupolar interaction: interstitial boron and boron on a lattice site with one germanium neighbour. Both these defects have C_{3v} symmetry around the $[111]$ axis of the lattice and are merely discriminated by the strength of the electric field gradient. This finding can be demonstrated in Fig. 1.

In principle, there are four $[111]$ directions in the T_d lattice which give rise to four resonances in the spectrum. As can be seen in Fig. 1, these resonances fall in one line if the $[100]$ axis of the crystal is aligned parallel to the external magnetic field. The resonance of the interstitial boron exhibits the greatest shift from the $2\nu_L$ value in the spectrum and is followed by the boron–germanium pair which has a weaker field gradient. The resonance line closer to $2\nu_L$ belongs to the substitutional boron atoms in the slightly distorted lattice.

The β -NMR resonance of the interstitial boron was observed first in pure silicon by Fischer et al. [9]. It is tempting to correlate this measured defect to the negative U-system which Watkins et al. [10,11] had described. Investigating different silicon-rich $Si_{1-x}Ge_x$ samples, we found that the resonance frequencies were independent of the germanium content. In all samples, a negative field gradient of $V_{zz} = -11.2(8) \text{ V/\AA}^2$ was measured, the value of which is in agreement with Fischer's result.

For the attributed defect complex, two different configurations are in discussion. Watkins suggested a positively charged boron which is located in the bond-centre between two silicon atoms [10], whereas recently DFT calculations [12] supported the configuration originally proposed by Tarnow et al. [13]. Here, a two-fold positively charged silicon in the interstitial is bonded to a negative boron which remains close to a regular lattice site. This configuration is shown in Fig. 2.

Fig. 1. Quadrupole resonances in the β -NMR spectrum for the $\nu_{-1/2 \rightarrow +1/2}$ transitions in a mixed crystal with 7at% germanium content at room temperature.

Fig. 2. Proposed configuration for interstitial boron.

In order to take the measured field gradient value to decide between the two configurations, we carried out the full-potential DFT calculations using the program package WIEN97 [14]. This code is based upon the density functional theory [15], the Kohn–Sham formalism [16] and the linearised augmented plane waves method [17]. For the exchange and correlation potential, the representation of Perdew et al. [18] was used. Additionally, a Newton algorithm was introduced to find the configuration in the minimum of energy.

The configurations were calculated in an array of 8, 9 atoms, respectively, which were subjected to the symmetry conditions mentioned above. In each Newton cycle these symmetries were maintained and, in addition, the bond-centre configuration of boron was to conserve the inversion symmetry. The atom positions were changed until the forces converged to a value lower than $0.5 \text{ mRy}/a_0$.

For both configurations, we found negative electric field gradients. An overview of the results of the measurements and calculations is given in Table 1. In the first two rows of the table, the bond lengths and the field gradients were calculated at the minimum of total energy, while in the last two rows, the field gradients were calculated by the WIEN code maintaining the bond lengths which are given in the reference papers. As an illustration of the results, contour plots of the calculated electronic charge densities in the $[110]$ planes of the lattice are shown in Figs. 3 and 4. For both configurations, the cigar-like enhanced charge densities around boron ions indicate negative field gradients.

Now we try to make a decision between the two proposed configurations from a comparison between the measured and calculated field gradients. It is obvious from the table that extremely short boron–silicon bonds and consequently high field gradient values are necessary to establish the bond-centre configuration. The calculated field gradient of $V_{zz} = -47.0 \text{ V/\AA}^2$ greatly exceeds the measured value. For Tarnow's configuration our calculation yielded $V_{zz} = -7.3 \text{ V/\AA}^2$. All boron–silicon bonds are found to be larger than 2.03 \AA . We

mention that, in this configuration, the field gradient significantly depends on the out-of-axis bond lengths and might be adjusted to the measured value by changing the lengths. In conclusion, we like to propose that the observed resonance is more likely caused by a defect configuration similar to Tarnow's suggestion.

In a second experiment, the details of which will be given in a forthcoming publication, we found the formation of boron–germanium pairs in silicon-rich mixed crystals. In the β -NMR measurements we found a field gradient of $V_{zz} = 3.8(3) \text{ V/Å}^2$. Our DFT calculations lead to a value of $V_{zz} = 3.1 \text{ V/Å}^2$ at the minimum of the total energy of the system. As this value is in reasonable agreement with the measured field gradient, the above attribution is considered to be confirmed. With reference to the undisturbed pure crystals, bonds are smaller when boron is the partner in the pair configurations. However, the boron–silicon bond does not go below $d = 2.16 \text{ Å}$. This result may be taken as a further support for the preference of Tarnow's configuration.

In conclusion, we point out that the combination of measurements and full-potential model calculations was necessary for the identification of defect complexes and

provided insight in the geometric and electronic structures of these defects.

Interstitial oxygen in GeSi alloys

I. Yonenaga*, M. Nonaka, N. Fukata

Institute for Materials Research, Tohoku University, Katahira 2-1-1, Aoba-ku, Sendai 980-8577, Japan

Abstract

Interstitally dissolved oxygen atoms in the Czochralski-grown $\text{Ge}_{1-x}\text{Si}_x$ were investigated by the infrared spectroscopy together with the analysis by the secondary ion mass spectroscopy and the X-ray fine structure. In GeSi alloys in the whole composition range $0 < x < 1$, oxygen atoms occupy preferentially a bond-center site between Si atoms to make a Si–O–Si quasi-molecule leading to a typical 1106 cm^{-1} peak. The 1106 cm^{-1} peak shifts to low frequency side with an increase in Ge, possibly due to the expansion of Si–Si bonds. © 2001 Elsevier Science B.V. All rights reserved.

Keywords: Germanium–silicon alloys; Oxygen; Infrared spectroscopy; Crystal growth

1. Introduction

Germanium–silicon ($\text{Ge}_{1-x}\text{Si}_x$) alloy is a fully miscible solid solution of the diamond-base and has attracted keen interest as material for applications such as both microelectronic and opto-electronic devices with various unique properties due to the band gap and lattice parameter variations according to the composition [1]. GeSi alloy crystals have been successfully grown by the Czochralski technique from a melt prepared in a quartz crucible [1–5]. A large number of oxygen atoms are incorporated into the grown crystals due to the chemical reaction between Si melt and quartz crucible [4]. Oxygen is one of the most important impurities in Si from both the practical and fundamental points of view. It is well known that oxygen atoms dissolve interstitially in Si in the concentration of about 10^{18} cm^{-3} in maximum concentration and occupy a bond-off center site between Si atoms. Such a Si–O–Si quasi-molecule causes the anti-symmetric stretching vibration around 1106 cm^{-1} at room temperature. Similarly, in Ge, oxygen occupies the similar site to make a Ge–O–Ge [6], but the concentration is more than two orders of magnitude lower in Ge than in Si. Far less is known about oxygen impurities in GeSi except only for Si-rich cases higher than $x = 0.93$

as reported by Kaneta-Yamada et al. [7] and Wauters and Clauws [8].

This paper reports the infrared spectroscopy investigation of interstitially dissolved oxygen atoms in the Czochralski-grown $\text{Ge}_{1-x}\text{Si}_x$ alloy crystals in the complete composition range ($0 < x < 1$). The results are discussed together with the total oxygen concentration obtained by the secondary ion mass spectroscopy (SIMS) and the local atomic structure by the extended X-ray fine structure (XAFS) studies [9].

2. Experiments

High purity bulk crystals of $\text{Ge}_{1-x}\text{Si}_x$ alloys across the whole composition range $0 < x < 1$ were grown by the Czochralski technique at very low pulling rates ranging from 1 to 8 mm/h in a flowing Ar gas atmosphere. The details are described in previous papers [1–5]. Samples for experiments were prepared from the as-grown boules of both single crystals of GeSi alloy in the composition ranges $0 < x < 0.15$ and $0.85 < x < 1$ and polycrystals in the composition range $0.15 < x < 0.85$. The composition of the grown alloys was determined by means of energy dispersive X-ray (EDX) analysis.

The infrared absorption in the alloys was observed at room temperature (RT) and at 5 K by means of a Fourier transform infrared (FT-IR) spectrophotometer

using JEOL-100 and BRUKER-IFS66 V apparatus with a liquid helium cryostat, respectively.

3. Results and discussion

Fig. 1 shows the infrared absorption spectra of the grown $\text{Ge}_{1-x}\text{Si}_x$ alloys of various Si content x , obtained at RT. The remarkable, broad peak was observed at the position centered around 1106 cm^{-1} , which originate on the anti-symmetric stretching vibration of interstitially dissolved oxygen atoms between Si atoms, Si–O–Si. The absorption coefficient $3\text{--}4\text{ cm}^{-1}$ was measured in Si-rich GeSi alloys, meaning that a large number of interstitial oxygen atoms are being included in the alloys. The peak intensity decreases with a decrease in the Si content x and then the peak almost disappears in the alloys with x lower than 0.23. In addition, with decreasing x the peak position shifts to the low wave number side. No peak at 855 cm^{-1} originating from Ge–O–Ge vibration was detected even in Ge-rich GeSi alloys. Moreover, there is no peak in the wave number range $1106\text{--}855\text{ cm}^{-1}$. At 5 K the main peak originating from Si–O–Si vibration shifts to the high frequency side and no other peak is observed in the above-mentioned wave number range. Thus, it seems that no peak originating into Si–O–Ge quasi-molecule exists in GeSi alloys.

Fig. 2 shows the absorption coefficient of the peak around 1106 cm^{-1} as a function of alloy composition. In the figure, the total amount of oxygen atoms in the GeSi alloys, determined by SIMS using Cs^+ induced at 10 kV, is also shown. The peak intensity corresponds well to the change of the total oxygen concentration determined by SIMS, which means that almost all the oxygen atoms in the alloys are present as interstitially dissolved atoms, but not as precipitates. As seen in Fig. 2, their dependences on the alloy composition fit well with the relation Ax^2 , where A is a constant. The results seem to show that the oxygen concentration depends strongly on

the ratio of Si–Si bonds in GeSi alloy with respect to the composition, if Si and Ge atoms occupy the lattice sites randomly. In fact, the XAFS investigations show the random substitutional site occupancy of Si and Ge atoms and no preferential ordering of the Ge–Ge dimer across the complete composition range [9]. We find that an oxygen atom preferentially occupies the bond-centered position of Si–Si bonds, forming Si–O–Si centers. Probably oxygen atoms have a stronger interaction with Si atoms than with Ge ones. From the correlation between the peak intensity and oxygen concentration, the calibration factor is estimated to be $5 \times 10^{17}\text{ cm}^{-2}$.

As seen in Fig. 3, the maximum peak around 1106 cm^{-1} shifts to the low wave number side linearly with the alloy composition in the complete range. In comparison with the previous results on Si-rich GeSi alloys reported by Kaneta-Yamada et al. [7] and Wauters and Clauws [8], also shown in the figure, the change rate is rather weak. The XAFS investigation [9] shows the following: First, the Ge–Ge and Ge–Si bond

Fig. 2. The absorption coefficient of the peak around 1106 cm^{-1} as a function of alloy composition together with the oxygen concentration measured by SIMS. The broken line shows the ratio of Si–Si bonds in GeSi.

Fig. 1. Infrared absorption spectra of the as-grown $\text{Ge}_{1-x}\text{Si}_x$ alloys of various Si content x , measured at RT.

Fig. 3. Shift of the 1106 cm^{-1} peak as a function of alloy composition together with those reported by Yamada-Kaneta et al. [7] and Wauters and Clauws [8].

lengths in GeSi alloys increase linearly, being parallel to each other, with decreasing Si content. Possibly the Si–Si bonds, not investigated, have the same dependence on composition in analogy with the Ge–Ge and Ge–Si cases. Second, the bonding feature in bulk GeSi alloys is close, but not completely, to the Pauling limit [10] rather than the Vegard limit [11]. From these XAFS results, it is known that most of the strain in GeSi alloys may be accommodated by changes in the bond length and bond angle. Yamada-Kaneta et al. [7] and Wauters and Clauws [8] pointed out that the peak shift of 1106 cm^{-1} to lower wave numbers is attributed to Si–O–Si vibration perturbed on Ge atoms at second and third neighbor sites with changing coupling strength. Here, besides this mechanism an increase of the Si–Si bond length with the decrease of Si content may be included.

4. Conclusion

Interstitally dissolved oxygen atoms in $\text{Ge}_{1-x}\text{Si}_x$ crystals in the whole composition range ($0 < x < 1$) grown by the Czochralski method were investigated by means of FT-IR, SIMS and XAFS. Only a typical peak at 1106 cm^{-1} originating from the vibration of Si–O–Si molecule was detected for the complete composition range. Oxygen atoms are known to occupy preferentially a bond-center site between Si atoms and to make Si–O–Si quasi-molecules in GeSi alloys. The expansion

of Si–Si bonds with an increase in Ge content may lead to a shift of the 1106 cm^{-1} peak of the Si–O–Si vibration to lower wave numbers.

Self-diffusion of ^{71}Ge in Si–Ge

A. Strohm^a, T. Voss^b, W. Frank^{a,b,*}, J. Räisänen^c, M. Dietrich^d^aMax-Planck-Institut für Metallforschung, Heisenbergstraße 1, D-70569 Stuttgart, Germany^bInstitut für Theoretische und Angewandte Physik, Universität Stuttgart, D-70550 Stuttgart, Germany^cDepartment of Physics, University of Jyväskylä, FIN-40351 Jyväskylä, Finland^dTechnische Physik, Universität des Saarlandes, D-66041 Saarbrücken, Germany

Abstract

The self-diffusivity D of implanted ^{71}Ge in relaxed, monocrystalline $\text{Si}_{1-y}\text{Ge}_y$ epi-layers has been measured as a function of temperature T ($894^\circ\text{C} \leq T \leq 1263^\circ\text{C}$) and composition y ($0 \leq y \leq 1$) by means of a radiotracer technique, where serial sectioning was done by ion-beam sputtering. For all compositions, the T -dependence of D is of Arrhenius type. The y -dependencies of both the diffusion enthalpy and the pre-exponential factor of D show a break at $y \approx 0.25$, which is ascribed to a transition from interstitialcy- ($y < 0.25$) to vacancy- ($y > 0.25$) mediated ^{71}Ge self-diffusion. © 2001 Elsevier Science B.V. 1. Introduction

Recently, a renaissance of Si–Ge alloys in semiconductor device technology has taken place because of the following reasons. Their charge carrier mobility and their band structure can be altered by changing the composition. For their device integration, the conventional and hence inexpensive silicon technology can be used.

A firm knowledge of the diffusion in Si–Ge alloys is highly desirable. On the one hand, doping with group-III and group-V elements for engineering the electric properties involves diffusion; on the other hand, the unintended in-diffusion of impurities has to be avoided.

Concerning diffusion in alloys, its dependencies on temperature and composition are of major interest. This is particularly so for Si–Ge, since different mechanisms of intrinsic-point-defect-mediated diffusion operate in its components [1]. This is due to the fact that under thermal-equilibrium conditions, in Ge, vacancies are the

only defect species, whereas in Si, vacancies and self-interstitials co-exist. More specifically, in Ge, self-diffusion takes place via vacancies in the entire regime of solid-state temperatures; in Si, self-diffusion is self-interstitial-controlled above about 1000°C and vacancy-controlled at lower temperatures. This implies that in Si–Ge, the mechanisms of self-diffusion change as a function of composition. This change can be investigated since the system Si–Ge does not have a gap of miscibility.

Already in 1974, McVay and DuCharme [2] published data on the self-diffusion of ^{71}Ge in polycrystalline Si–Ge. Within a research project of the present authors, the self-diffusivities of both ^{71}Ge and ^{31}Si in monocrystalline Si–Ge epi-layers are measured. First results on the diffusion of ^{71}Ge are presented in this paper.

2. Experiments

The specimens used in the present investigations were $7 \times 7 \text{ mm}^2$ platelets sawn out from the following three kinds of relaxed, monocrystalline $\text{Si}_{1-y}\text{Ge}_y$ epi-layers, all

*Corresponding author. Tel.: +49-711-689-1940; fax: +49-711-689-1922.

E-mail address: wfrank@mf.mpg.de (W. Frank).

of which were intrinsic and had been grown from the vapour phase on (100)-oriented substrates:

- (i) $\text{Si}_{0.95}\text{Ge}_{0.05}$, 10 μm thick, grown at 1100°C at the Institute of Electronics of the Academy of Sciences of Uzbekistan in Tashkent. The density of the threading dislocations in the epi-layers was estimated to be 10^{10} m^{-2} from the pit densities on Secco-etched surfaces by optical microscopy.
- (ii) $\text{Si}_{0.90}\text{Ge}_{0.10}$, 0.4 μm thick, and $\text{Si}_{0.75}\text{Ge}_{0.25}$, 1.05 μm thick, grown on the substrates after deposition of a 10 nm thick Si-buffer layer by Okmetic Ltd., Vantaa, Finland. The density of the threading dislocations in the epi-layers was found to be less than 10^9 m^{-2} by transmission electron microscopy.
- (iii) $\text{Si}_{0.57}\text{Ge}_{0.43}$, 0.45 μm thick and virtually dislocation-free, grown on the substrates after deposition of an about 2 μm thick graded Si–Ge buffer layer at DaimlerChrysler Forschungszentrum, Ulm, Germany.

The diffusion studies were performed by means of a modified radiotracer technique, in which the ^{71}Ge -tracer atoms were implanted with an energy of 60 keV into the Si–Ge epi-layers in a non-channeling direction to depths between 30 and 40 nm at the mass separator of the Institut für Strahlen und Kernphysik at Bonn University, Germany, or at the on-line isotope separator (ISOLDE) of the European Organization for Nuclear Research (CERN) in Geneva, Switzerland.

The implanted specimens were cleaned in acetone, RCA I, RCA II, and citric acid, shortly dipped into HF, and finally rinsed with high-purity water. Then they were sealed up in HSQ-300 quartz ampoules under 15% H_2 –85% Ar atmosphere of 99.9999% purity, after these had been purified in HNO_3 –HCl (1:3) and HF. Next the specimens were isothermally diffusion-annealed in the temperature range of 894–1263°C. The durations of annealing lay in the regime from 2 h to 30 days, whose upper limit was dictated by the ^{71}Ge half-life of 11.2 days. Proceeding in this way guarantees that the thickness of the oxide growing on the epi-layers during diffusion annealing is less than 5 nm, and thus the implanted tracer atoms do not get stuck in the surface oxide.

After diffusion annealing, the ^{71}Ge distributions in the Si–Ge epi-layers were measured along the depth coordinate x perpendicular to the epi-layer surface $x = 0$. To this end, the specimens were serially sectioned by ion-beam sputtering at rates ranging from 6 to 10 nm/min. By sectionwise counting the ^{71}Ge atoms in the removed material, which was done by monitoring the radioactivity of the ^{71}Ge decay, it was possible to construct the ^{71}Ge concentration profiles $C(x)$ in the diffusion-annealed specimens. Implantation profiles in non-diffusion-annealed specimens were measured in the same way.

Fig. 1. ^{71}Ge -profiles in $\text{Si}_{0.95}\text{Ge}_{0.05}$ produced by 60 keV-implantation (\square) and subsequent diffusion annealing at 1095°C for 18 h (\bullet). The curve is a fit of an appropriate solution of the diffusion equation to the diffusion profile.

Fig. 2. Arrhenius presentation of self-diffusion coefficients of ^{71}Ge in $\text{Si}_{1-y}\text{Ge}_y$ (\blacktriangledown , $y = 0$, bulk; \cdots , $y = 0$, bulk [3]; \blacksquare , $y = 0.05$, epi-layers; \square , $y = 0.1$, epi-layers; \bullet , $y = 0.25$, epi-layers; \circ , $y = 0.43$, epi-layers; \blacklozenge , $y = 0.95$, bulk; $---$, $y = 1.0$, bulk [4]; \blacktriangle , $y = 1.0$, bulk).

3. Results

Examples of an implantation profile and a diffusion profile are presented in Fig. 1. By fitting an appropriate solution of the diffusion equation to the diffusion profiles, self-diffusion coefficients for ^{71}Ge in $\text{Si}_{1-y}\text{Ge}_y$, D , may be determined. The best fits were obtained for the semi-infinite-space ($x \geq 0$) solution, which contains the implantation profile for the corresponding Ge-content as initial condition, when total reflection of the diffusers at the surface $x = 0$ was assumed.

Fig. 2 shows D as a function of the diffusion temperature T for various compositions y . Obviously,

Table 1

Self-diffusion enthalpies H and pre-exponential factors D_0 of self-diffusion coefficients for ^{71}Ge in $\text{Si}_{1-y}\text{Ge}_y$ with various Ge-contents y

y	0.00	0.05	0.10	0.25	0.43	0.95	1.00
H (eV)	4.97	4.9	4.7	4.1	4.0	3.3	3.09
D_0 ($\text{m}^2 \text{s}^{-1}$)	0.25	0.4	0.04	0.0033	0.0029	0.01	0.00136

D obeys Arrhenius laws:

$$D = D_0 \exp(-H/kT), \quad (1)$$

for all compositions investigated (k = Boltzmann's constant). The corresponding diffusion enthalpies H and pre-exponential factors D_0 are compiled in Table 1. For comparison, data from the literature on the diffusion of ^{71}Ge in bulk Si ($y = 0$) [3] and bulk Ge ($y = 1$) [4] as well as own data on the ^{71}Ge -diffusion in (111)-oriented, highly dislocated, intrinsic bulk $\text{Si}_{0.05}\text{Ge}_{0.95}$ are included in Fig. 2 and Table 1. Apparently, these bulk-diffusion data are in accordance with our diffusion data on epi-layers. To demonstrate the agreement of our diffusion data with those of other authors [3,4], the ^{71}Ge -diffusivities in (111)-oriented bulk Si at 1200°C and in (100)-oriented bulk Ge at 748°C measured in the present work are also shown in Fig. 2.

The composition dependence of the ^{71}Ge -diffusion in $\text{Si}_{1-y}\text{Ge}_y$ is of particular interest. Fig. 3 illustrates how the diffusion enthalpy and the pre-exponential factor of the diffusion coefficient depend on the Ge-content. Either curve shows a break at the same Ge-content, viz., $y \approx 0.25$.

4. Discussion

The break in both the H - y and the D_0 - y curves we tentatively ascribe to the change from interstitial diffusion on the Si-side to vacancy diffusion on the Ge-side, which is expected according to Section 1. This interpretation is supported by other investigations to be reported below.

At first sight, the investigations of the ^{71}Ge -diffusion in polycrystalline Si-Ge of McVay and DuCharme, who also found breaks in the H - y and D_0 - y curves at a somewhat different composition ($y \approx 0.35$), seem to confirm our observations. However, one should bear in mind that several findings of McVay and DuCharme are not understood. For $y < 0.5$, the $\log D - x^2$ plots of their diffusion profiles show a kink separating a steeper surface-near part from a deep-reaching tail, where the surface-near part shrinks with increasing Ge-content and disappears completely for $y > 0.5$. Evaluating the tails of their profiles, McVay and DuCharme found D -values, which for all temperatures and compositions distinctly exceed ours and those of other authors [3,4].

Fig. 3. Self-diffusion enthalpy H (full symbols) and pre-exponential factor D_0 (empty symbols) of the diffusion coefficient for ^{71}Ge in $\text{Si}_{1-y}\text{Ge}_y$ as functions of the Ge-content y (down-triangles, bulk [3]; circles, epi-layers; squares, bulk; up-triangles, bulk [4]).

These ambiguities raise doubts on whether McVay and DuCharme's data truly confirm our results.

Sb is a substitutional solute that, in contrast to ^{71}Ge , diffuses via vacancies in both Si [5] and Ge [6]. Hence, one expects that for Sb in $\text{Si}_{1-y}\text{Ge}_y$ neither occurs a break in the H - y nor in the D_0 - y curve. This has been tested in diffusion measurements of Sb in relaxed Si-Ge epi-layers by Nylandsted Larsen and Kringhøj [7]. Whereas the uncertainty of their D_0 -values inhibits to determine reliably the dependence of D_0 on y , H decreases monotonically from Si to Ge indeed.

Fischer et al. [8] have measured the diffusivity of ^{195}Au in $\text{Si}_{1-y}\text{Ge}_y$ up to $y = 0.24$. They found that in this composition range ^{195}Au undergoes kick-out-type diffusion. This involves exchanges of ^{195}Au between substitutional (Au_s) and interstitial (Au_i) sites according to

which are mediated by self-interstitials (I). Hence, even below 1000°C, where Fischer and collaborators' diffusion studies of ^{195}Au in Si-Ge were carried out, and up to a Ge-content of 24%, self-interstitials are present under thermodynamic equilibrium conditions. This result is compatible with our view that ^{71}Ge self-diffusion in $\text{Si}_{1-y}\text{Ge}_y$ is controlled by self-interstitials up to $y \approx 0.25$, where the curves in Fig. 3 show a break.

Further studies of diffusion in $\text{Si}_{1-y}\text{Ge}_y$ have been performed by Kuo et al. [9]. These authors report that

on the Si-side, in contrast to what is true for ^{71}Ge , for B-diffusion, H and D_0 increase with increasing Ge-content. This seeming conflict is resolved if, following Kuo et al., their B-data are interpreted in terms of a slowing down of the B-atoms by temporary trapping at Ge-sites. In fact, according to Koiwa [10], for this kind of retarded diffusion the $H - y$ and $D_0 - y$ dependencies observed by Kuo et al. are predicted.

Acknowledgements

The authors are grateful to N. Abrosimov, V.-M. Airaksinen, T. Hackbarth, and K. Lyutovich for the production of the Si–Ge material and to D. Eversheim for his assistance during the ^{71}Ge -implantation at Bonn University. Moreover, ^{71}Ge -implantations at ISOLDE, CERN, as well as financial support by the Academy of Finland (project 44875) and the HPRI Programme of the European Community are appreciated.

Low temperature muonium behaviour in Cz-Si and Cz-Si_{0.91}Ge_{0.09}

P.J.C. King^{a,*}, I. Yonenaga^b^a *ISIS Facility, Rutherford Appleton Laboratory, Chilton, Oxfordshire, OX11 0QX, UK*^b *Institute for Materials Research, Tohoku University, Sendai 980-8577, Japan*

Abstract

Observation of muon and muonium behaviour in semiconducting materials provides valuable insight into analogous hydrogen states and dynamics. We have used muon spin rotation, relaxation and resonance techniques to observe the low-temperature muon behaviour in Czochralski-grown silicon and bulk, Czochralski-grown silicon-germanium alloy materials. Low temperature relaxation of the rapidly moving tetrahedral muonium species and its conversion to a diamagnetic species is seen in the Cz material but not in the float zone silicon, suggesting site change and subsequent ionisation are promoted by the oxygen impurity. This is also the first time muon behaviour in a Si_{1-x}Ge_x alloy material has been presented. © 2001 Elsevier Science B.V. All rights reserved.
